Furthermore, while relying more and more on technology, people are increasingly less prepared to tolerate the risk that this involves. The problem of safety is therefore difficult and ongoing.

2.1. Risk

Risk is an uncertain, possible event, and, as regards safety, often involves damage.

Damage occurs when a harmful agent, finding a medium favorable to its production and/or propagation, reaches a receptive site, i.e., a target.

Safety objectives are designed to prevent the formation of harmful agents, to confine them so as to prevent their dispersal, or to ensure that receptive sites are beyond their reach. Safety measures often combine these objectives. Elaboration of these measures involves analysis of the various parameters and their evolution over time. This risk identification requires a constant questioning approach, e.g., what can a harmful agent do? What can be done to prevent it?

All possibilities should be explored: normal operation, incident, and accident, up to a possible serious catastrophe; in each case measures have to be devised to prevent the situation becoming worse and to reduce damage. Such a method is effective only if it covers all the stages (e.g., in an industrial installation the design, execution, and operation) and involves all factors in these stages.

Risk identification should be supplemented by an evaluation of the probability that the risk will occur. A risk is fully defined only by the conjunction of its detrimental effects and its probability; this enables risks to be compared. Statistical methods enable such an evaluation to be made, and although these methods are still imperfect and limited, especially in new fields, they are improving all the time.

One method that applies particularly to fixed installations is that based on experimental feedback. Starting from an analysis of incidents by the method of event trees, it evaluates the probability that such events may degenerate into a serious accident, and by adding these probabilities over a period of time and referring the result to the number of installations of the same type, it can sometimes be shown that a serious accident becomes probable after a certain period. The importance of this method is that it is able to show that the safety of a system has become compromised, even though no accident has occurred and those responsible may honestly believe that the system is operating satisfactorily.

How can these principles be applied to the transport and storage of dangerous materials? First, this field concerns public safety, on account of the extent and potential consequences of accidents; in all developed countries, it is regulated. Regulations are generally national or local as regards production and storage or national or international as regards transport.

All regulations include an identification of dangerous materials and their classification according to the nature of the danger they present; classification consists of a list of products, drawn up on the basis of experience, and often supplemented by criteria and tests for new materials. These lists and criteria are not necessarily the same for storage and transport (e.g., carcinogenicity or toxicity by bioaccumulation are of little importance in connection with transport). Listing of a product means that the safety regulations applicable to the material and to the activity in question must be observed.

The regulations almost always include the following provisions:

1) Declaration and marking of materials: transport document (manifest) or storage declaration, and labeling of containers
2) Confinement: regulations covering the construction and testing of containers and tanks, safety systems, and warning systems
3) Operations: safety instructions for normal operation and in an accident
4) Environmental factors: distances of storage sites from places of habitation, regulations governing the construction and movement of transport vehicles

2.2. Transport Safety

Transport is an important stage in the life cycle of a dangerous material, which extends from its production to its use. Dangerous materials are scarcely handled at all during transport, except during loading and unloading; the materials are packed and not normally in direct contact with potential targets (humans, animals, the environment).

Accidents due solely to the material itself are therefore fairly rare; the risk comes from the medium in which the material is found, namely traffic. Those responsible for transport safety have to deal specifically with traffic accidents and the consequences arising from the presence of dangerous materials, attempting to reduce the probability of:

Traffic accidents
Escape of material in the event of an accident
Contact between the unconfined material and a target

The best way of preventing a transport accident is to avoid transport. This is why transport of some extremely dangerous materials (e.g. nondesensitized nitroglycerine) is prohibited. Manufacturing industries have to adapt their production methods to these demands.

Measures intended to reduce the probability of escape of material involve the use of the strongest possible containers (crates, boxes, tanks), not forgetting that, except in certain cases (e.g., containers for certain radioactive materials), they are unable to withstand major accidents, and that, if there is a fire, containers that are too strong can cause high pressures, resulting in explosions. Particularly for large containers, such as tanks, it is better to concentrate on their ability to deform without bursting when subjected to violent shock, rather than their overall strength. The ductility of the material and the amount of energy it absorbs on deformation are important safety factors, as is the provision of structures which distribute the deformation (rings, collars, baffles, etc.).

A compromise has to be reached in the solution of these complex problems, depending on the hazard level of the material, type of transport, and industrial technology, which is reflected in national and international transport regulations that lay down provisions and tests for containers.

In addition tanks, large bulk containers, and gas cylinders are subjected to periodic checks. Also, limits are placed on the amount of material per container in order to reduce the amount of material that can escape in the event of an accident. Some materials are not allowed to be transported in bulk. In limiting the amount of material carried per vehicle, it has to be remembered that this increases the number of vehicles transporting this material, and thus the probability of an accident. This type of provision is restricted almost exclusively to explosives.

Materials that can react with one another, causing a new additional danger, e.g., fire, explosion, release of toxic gas, must not be packed together. Similarly, it is prohibited to transport in the same vehicle materials (explosives and organic peroxides) that can cause an explosion with other dangerous materials, since dispersal of these materials by an explosion exacerbates their effects and hinders their recovery.

In order to reduce the probability of a traffic accident, the safety of vehicles is continually being improved, e.g. by improving braking (ABS system, heavy-duty brakes) or by lowering the center of gravity of tanks. Attempts are also being made to improve driver behavior by awareness and reflex training.

To reduce the probability of traffic accidents, and to prevent contact between unconfined material and a target, is more problematic, sometimes contradictory. For example, in the case of land transport there may be a choice between rail and road. It might seem preferable to chose rail since the overall probability of an accident is very low, but railway lines in general pass through built-up areas, whereas bypasses on trunk roads often avoid these.

Furthermore, railway stations, with their points crossings and intersections (i.e., in populated areas) involve the greatest probability of an accident. The amounts of dangerous materials transported in a train are much greater than those in a lorry, and much more varied, which gives rise to the possibility of much more serious accumulations and dangerous synergistic effects. The decisions taken by some countries in favor of rail transport are often politically or commercially motivated. Modes of transport can be compared only from case to case, between a specified starting point and destination.

The same applies when choosing one particular route over another. Local authorities are sometimes inclined to prohibit movement of certain dangerous materials within their built-up areas. Such a decision, which shifts the danger elsewhere, should be taken only on the basis of a comparative analysis of the risk of transport subject or not subject to such a prohibition. The decision should specify a recommended alternative route for transporting dangerous goods. The choice of such a route is complex, and should take account of the environment, avoid possible proximity of industrial activities capable of exacerbating a potential road accident, and avoid populated areas, taking account of daily journeys and travel (the commercial and business center of a large town contains many people during the day, whereas the suburbs are almost empty; the reverse is true at night).

Other types of more general prohibition or restriction exist, often decided at government level and concerning the days, or even hours, when road traffic is very heavy and/or the probability of accidents is very high (beginning and end of holidays, weekends, festivals, etc.). All these measures tend to channel the movement of dangerous goods into periods and zones where the probability and consequences of an accident are a minimum.

Another way to tackle the consequences of an accident is to improve the speed and efficiency of the emergency services. Studies are being carried out on the possibilities of satellite surveillance and warning.

2.3. Storage Safety

With regard to the production or storage of dangerous goods the drafting of the safety measures should take account of the agent, medium, and target. Identification of the agent appears simple. However, with regard to production as well as storage, when the length or conditions of storage can affect stability, all the possible forms and transformations of a material have to be examined. The major accident in a chemical factory in Seveso led to a European Community Regulation, the so- called Seveso Directive. The product, which was distributed over a large area by the accident, was an extremely toxic dioxin. No measures had been envisaged to control this compound, since it was not the end product of the process, but was formed only as an intermediate and converted immediately into a less dangerous chemical. No one had considered that an accident resulting in escape could occur during the brief existence of the dioxin. This graphically illustrates the need for extreme care in identifying the danger.

Unlike transport, the medium is geographically fixed, which simplifies matters, though its study should take into account all the possible variations: time of day; seasonal climatic conditions; wind speeds and directions, as well as all the normal, incidental, and unplanned operating conditions in the installation itself, so as to evaluate the forseeable consequences and formulate appropriate safety measures.

These measures vary, depending on the nature of the goods that are stored and the industrial activity, but always aim to reduce the risk of escape of dangerous products. They include restricting or splitting up amounts of materials, strengthening containers, verifying that they are in good condition by periodic checks, using devices to contain leaks, etc. It should also be ensured that the installation can withstand foreseeable natural catastrophes, including earthquakes, tornadoes, etc. Special attention should be paid to the operation of the installation. Any handling of the product is a dangerous operation on account of the risk of error. The human factor, despite technical progress, remains a decisive element in the uncertainty of risk calculations; there is an increasing tendency to reduce the human element by automation, and to create intrinsically safe systems which can "excuse" an operator error, and even restore normal operation in the case of an incident. Despite this, humans continue to be indispensable, which is why information and workforce training are necessary to reduce risk. Active participation of all those involved in designing safety measures should be encouraged since this is the best way of achieving a safety culture in the enterprise where people are no longer the weak link in the chain, but become the central positive element of the safety system.

In most cases of manufacture or storage of dangerous substances, the consequences of a serious accident may extent far beyond the confines of the enterprise. Its siting is therefore of primary importance, the ideal being to locate it

as far as possible from populated areas. Care should also be taken to ensure that, in the case of toxic gases, the prevailing winds are not in the direction of such areas, and that, in the event of accidental spillage, the impermeability of the ground prevents pollution of underground water.

The location of dangerous sites in relation to built-up areas often presents a problem. In most European countries, demographic trends in the last two decades have led to an often uncontrolled expansion of towns and cities, which is why previously well-isolated industrial installations are now within urban boundaries, with a frightening increase in risk. Even where new enterprises are sited in rural areas, it is sometimes found that public bodies responsible for land management do little to resist pressure from landowners who wish to divide into plots and sell land that has been developed for industrial purposes, sometimes to allow company employees to live near their place of work. It is very important that any enterprise involved in the manufacture or storage of dangerous materials be enclosed by an adequate safety perimeter, including the zone where the presence of houses and dwellings presents a serious risk in the event of an accident. The safety measures adopted by the company should include alerting and informing the population involved as well as the public authorities.

This is also prescribed in European Directive 82-501 (the Seveso Directive). This covers industrial establishments (other than nuclear, military, and waste disposal) that produce, use, or store amounts of dangerous materials above the levels specified in a list appended to the directive. The directive makes the manufacturer responsible for determining the risk, taking appropriate safety measures, and informing and training the workforce. The manufacturer should also notify the relevant authorities and keep an up-to-date list of the type and amount of dangerous materials being produced and stored; describe the installation and production processes; internal emergency procedures; and provide all the necessary information for the formulation of an external emergency plan by the official safety bodies. The manufacturer should notify the authorities of all major accidents, including the circumstances, materials involved, measures adopted and to be adopted; notification has to be followed by the setting up of a special enquiry.

The safety principles governing dangerous installations in Europe are fairly well defined and regulated. An important feature of these measures is that they require regular safety checks to be carried out by an independent outside body.

Any safety system, however well designed, will tend to deteriorate over time. Not only must the safety equipment and systems be regularly checked, serviced, and repaired, but instructions to the workforce and their level of awareness and training also need to be periodically updated. There are two periods when the risk associated with an installation is greatest: during start-up, since the safety systems have not yet been tested; and after a long incident-free period, when the risk has been minimized or even forgotten by managers and workers. This is why it is essential for a disinterested observer, if possible outside the company or at least completely independent of the production organization, to make periodic visits to evaluate the safety system and update the objectives, without however interfering in the choice of measures to be adopted to achieve these objectives, which should remain the responsibility of the management.

2.4. Security

Safety may be defined as the complete absence of risk. Zero risk is an objective which one must strive for, but which is never reached. In many languages, safety and security are virtually synonymous.

Economic imperatives must be taken into account in this constant striving to improve safety. Safety has its price. No reliable safety exists if the means, and thus the necessary funding, have not been allocated for this purpose. This implies that it should not be left unsupervised in the hands of those responsible for production.

Contrary to a widespread misconception, safety cannot be achieved regardless of cost. It is therefore unacceptable that safety regulations be drawn up by a remote bureaucratic system. Even in high-level international bodies, such a system tends to add new constraints without taking into account the probability of the risk that these constraints are designed to combat, their economic effects, or sometimes even their feasibility. It is possible to arrive at provisions that

are so complex and difficult to apply that they are not implemented.

The safety costs involved in the production, transport, and storage of a dangerous product cannot exceed a certain fraction of the internationally accepted value of the product. On the other hand, the industrial safety field is so complex that there are always several ways of achieving the same result. Accordingly, the aim of experts in this field, whether they be regulatory bodies or industrial managers, should be to avoid implementing measures indiscriminately, even if they are ostensibly aimed at security, but instead choose the measures that have the best cost/benefit ratio.

Industrial safety, whether of persons or the environment, has become a political football for decision-makers and an economic debate among manufacturers. There may thus be a temptation for the former to emphasize the "public relations" impact to the detriment of efficiency, and for the latter to promote eye- catching features in order to maximize profit, all this often being supported by the media, which tend to seek sensationalism rather than objective information. Sometimes, under the pretext of safety, measures may be accepted that would otherwise have been rejected, or decisions are made purely on economic grounds.

Although these comments may appear rather pragmatic, it should not be forgotten that safety research is eminently worthwhile, even if it demands a great deal of perseverance, attention to detail, and humility. One should never believe the experts when they say, "We have done everything we can," one must continue to question. Safety techniques improve at least as quickly as production techniques, which, in the end, is very reassuring.

3. Dangerous Goods and Substances

Test methods, classification, labeling, and assigning to packaging groups of dangerous goods should be harmonized worldwide for all modes of transport (sea, rail, road, and air).

The UN Recommendations cover all modes of transport. Where less stringent requirements can be applied to a particular mode, this is indicated only in special circumstances. For air transport, more stringent requirements may occasionally apply. The Recommendations are internationally implemented through regulations and agreements covering rail, road, sea, and air transport. The parts of the Recommendations which are relevant to this chapter are the definitions of classes, principles and criteria for classification, test methods, labeling, and the *List of Dangerous Goods Most Commonly Carried* (approximately 3000 entries). There is a great degree of flexibility in the data on which the classification is based, because the ultimate classification, i.e., designation of class and inclusion in the UN Recommendations list of substances (Chap. 2) is done by UNCETDG [9] which passes judgement on the data and the proposals for classification submitted to it. The UN system uses the notion of primary hazard, which determines the hazard class. This is reflected in the recommendation that "in general not more than one danger class label should be affixed to a package". If a substance meets the definition of more than one class, a rule of precedence applies, and a distinction is made between primary and subsidiary risks (see Sections 3.1 and 3.1.10).

Principles Underlying the Regulation of the Transport of Dangerous Goods. Transport of dangerous goods is regulated in order to prevent, as far as possible, accidents to persons or property and damage to the means of transport employed or to other goods. At the same time, regulations should be framed so as not to impede the movement of such goods, other than those too dangerous to be accepted for transport. With this exception, the aim of regulations is to make transport feasible by eliminating risks or reducing them to a minimum.

Classification and Definitions of Classes of Dangerous Goods. The classification of goods by type of risk involved has been drawn up to meet technical conditions while at the same time minimizing interference with existing regulations. Classifications are made on consideration of data submitted to the Committee by governments, intergovernmental organizations, and other international organizations.

Classification of Dangerous Wastes. Wastes should be transported under the requirements of the appropriate class, considering

their hazards and the criteria of the Recommendations. Wastes not otherwise subject to the Recommendations, but covered under the Basel Convention [10] may be transported under Class 9.

Many of the substances listed in Classes 1 – 9 are deemed, without additional labeling, to be environmentally hazardous.

In Germany, the classification of "dangerous wastes", "special wastes", "dangerous residuals", "oils from wastes", and "chemical wastes" can be made on the basis of the *Abfall-Transport-Berater*, which adopts a general view on the character of the wastes/residual substances and their classification in the ADR/RID (GGVS/GGVE), taking into account the *Abfallartenkatalog*. It enables the sender, to classify such substances without too much effort [11].

Determination of the Physical State. Unless there is an explicit or implicit indication to the contrary in the UN Recommendations, dangerous goods with a melting point or initial melting point of 20 °C or lower at a pressure of 101.3 kPa are considered to be liquids. A viscous substance for which a specific melting point cannot be determined should be subjected to the ASTM D 4359-90 test; or the test for determining fluidity (penetrometer test) prescribed in Appendix A.3 of Annex A of the *European Agreement Concerning the International Carriage of Dangerous Goods by Road* (ADR) with the modifications that the penetrometer should conform to ISO 2137: 1985, and that the test should be used for viscous substances of any class.

Goods too Dangerous to be Carried Without Special Restrictions. Inherent instability of goods may involve different hazards, e.g., explosion, polymerization with intense evolution of heat, or emission of toxic gases. In most substances, such tendencies can be controlled by correct packing, dilution, stabilization, addition of an inhibitor, refrigeration, or other precautions.

Where (bearing in mind the manner in which such items are generally packed) precautionary measures are laid down for a given substance or article (e.g., that it should be "stabilized" or "inhibited") such substance or article should not normally be carried when these measures have not been taken.

Collective Entries. National or international regulations may list, either as single or as suitable collective entries, substances or articles which do not appear in the Recommendations. A "generic" or "not otherwise specified" entry (N.O.S. entry) may be used to permit the transport of substances or articles which do not appear specifically by name in the list of dangerous goods. Such a substance or article may be transported only after its dangerous properties have been determined. Any substance or article having or suspected of having explosive characteristics should first be considered for inclusion in Class 1. Some collective entries may be of the generic or N.O.S. type, provided the regulations contain provisions ensuring safety, both by excluding extremely dangerous goods from normal transport, and by covering all subsidiary risks inherent in some goods.

Classification of Solutions and Mixtures. A mixture or solution containing a dangerous substance identified by name in the Recommendations and one or more substances not subject to the Recommendations should be treated according to the requirements given for the dangerous substance, provided the packaging is appropriate to the physical state of the mixture or solution, unless:

1) The mixture or solution is specifically identified by name in the Recommendations; or
2) The entry in the Recommendations indicates that it applies only to the pure substance; or
3) The hazard class, physical state, or packing group of the solution or mixture is different from that of the dangerous substance; or
4) There is significant change in the measures to be taken in emergencies.

For a solution or mixture of which the hazard class, physical state, or packing group differs from that of the listed substance, the appropriate N.O.S. entry should be used, including its packaging and labeling provisions.

3.1. Transport Classification of Dangerous Goods

UN Classes and Divisions are summarized as follows:

Class	1	Explosives
	1.1	Substances and articles which have a mass explosion hazard
	1.2	Substances and articles which have a projection hazard, but not a mass explosion hazard
	1.3	Substances and articles which have a fire hazard and either a minor blast hazard or a minor projection hazard, or both, but not a mass explosion hazard
	1.4	Substances and articles which present no significant hazard
	1.5	Very insensitive substances which have a mass explosion hazard
	1.6	Extremely insensitive articles which do not have a mass explosion hazard
Class	2	Gases: compressed, liquefied, dissolved under pressure, or refrigerated
Class	3	Flammable liquids
Class	4.1	Flammable solids: readily combustible solids, self-reactive substances, wetted explosives
Class	4.2	Substances liable to spontaneous combustion: pyrophoric substances, self-heating substances
Class	4.3	Substances, which in contact with water, emit flammable gases
Class	5.1	Oxidizing substances
Class	5.2	Organic peroxides
Class	6.1	Toxic substances
Class	6.2	Infectious substances
Class	7	Radioactive material
Class	8	Corrosives
Class	9	Miscellaneous dangerous substances

General Provisions of ADR/RID. Annex A of ADR or Annex I of RID specifies the dangerous goods to be excluded from international carriage by road and the dangerous goods to be accepted for such carriage under certain conditions. It groups the dangerous goods in restrictive and nonrestrictive classes. Of the dangerous goods covered by the restrictive classes (Classes 1, 2, and 7) those which are listed in the clauses concerning these classes are to be accepted for carriage only under the conditions specified; others are excluded from carriage. Some of the dangerous goods covered by the nonrestrictive classes (Classes 3, 4.1, 4.2, 4.3, 5.1, 5.2, 6.1, 6.2, 8, and 9) are excluded from carriage; of the other goods covered by the nonrestrictive classes, those which are mentioned in the clauses concerning these classes are to be accepted for carriage only under the conditions specified; those not mentioned or covered by one of the collective headings are not deemed to be dangerous goods and are to be accepted for carriage without any special conditions.

ADR/RID Classes and Divisions. Hazard categories and terms used in the Regulations concerning the International Carriage of Dangerous Goods by Road and Rail (RID/ADR) [12] are summarized below.

Class 1	Explosive substances and articles	Restrictive
Class 2	Gases: compressed, liquefied, or dissolved under pressure	Restrictive
Class 3	Flammable liquids	Nonrestrictive
Class 4.1	Flammable solids	Nonrestrictive
Class 4.2	Substances liable to spontaneous combustion	Nonrestrictive
Class 4.3	Substances which, in contact with water, emit flammable gases	Nonrestrictive
Class 5.1	Oxidizing substances	Nonrestrictive
Class 5.2	Organic peroxides	Nonrestrictive
Class 6.1	Toxic substances	Nonrestrictive
Class 6.2	Infectious substances	Nonrestrictive
Class 7	Radioactive material	Restrictive
Class 8	Corrosive substances	Nonrestrictive
Class 9	Miscellaneous dangerous substances and articles	Nonrestrictive

From 1 January 1995, the classification criteria concerning flammable liquids are the same worldwide; the upper flash point limit is $\leq 61\ ^\circ C$ c.c. (closed cup test).

Hazard Categories and Terms used in the International Maritime Dangerous Goods Code (IMDG-Code) [13]. Regulation 2 of part A of Chapter VII of the *International Convention for the Safety of Life at Sea, 1974*, as amended, sets out the various classes of dangerous goods. For the purposes of the Code, it has been found necessary to subdivide a number of these classes and to define in greater detail the characteristics and properties of the substances, materials, and articles which fall within each class or division. In accordance with the criteria for selection or marine pollutants for the purposes of Annex III of the *International Convention for the Prevention of Pollution from Ships, 1973*, as modified by the Protocol of 1978 (MARPOL 73/78), a number of dangerous substances in the various classes have also been identified as substances harmful to the marine environment (Marine Pollutants, see 3.1.11).

IMO Classes and Divisions. For the following classes, the IMDG-Code differs from the UN Recommendations and the RID/ ADR:

Class 3. Flammable liquids are defined as liquids, mixtures of liquids, or liquids containing solids in solution or suspension (e.g., paints, varnishes, lacquers, but not including substances which, on account of other dangerous characteristics, have been included in other classes), which give off a flammable vapor at or below 61 °C (141 °F) closed cup (c.c.) test (corresponding to 65.6 °C (150 °F) open cup test).

In the IMDG-Code, Class 3 is further subdivided:

Class 3.1. Low-flash-point liquids; flash point < -18 °C (0 °F) c.c.

Class 3.2. Intermediate-flash point liquids; flash point from -18 °C (0 °F) up to, but not including, 23 °C (73 °F) c.c.

Class 3.3. High-flash-point liquids; flash-point from 23 °C (73 °F) up to, and including, 61 °C (141 °F) c.c.

Substances with flash point $>$ 61 °C (141 °F) c.c., are not considered dangerous by virtue of their fire hazard, where the flash point is indicated for a volatile liquid it may be followed by the symbol "c.c.", representing determination by a closed cup test, or by "o.c.", representing an open cup test. A reference to these tests is given in Section 6 of the General Introduction of the IMDG-Code.

3.1.1. Explosive Substances and Articles (Class 1)

UN Recommendations. Class 1 comprises:

1) Explosive substances (a substance which is not itself an explosive, but which can form an explosive atmosphere of gas, vapor, or dust is not included in Class 1), except those that are too dangerous to transport, or those where the predominant hazard is appropriate to another class;
2) Explosive articles, except devices containing explosive substances in such quantity of or such a character that their inadvertent or accidental ignition or initiation during transport causes no effect external to the device either by projection, fire, smoke, heat, or loud noise; and
3) Substances and articles not mentioned under (1) and (2) which are manufactured with a view to producing a practical, explosive, or pyrotechnic effect.

Transport of explosive substances which are unduly sensitive or so reactive as to be subject to spontaneous reaction is prohibited.

Under the UN Recommendations, the following definitions apply:

1) An explosive substance is a solid or a liquid substance (or a mixture of substances) which is in itself capable by chemical reaction of producing gas at such a temperature and pressure and at such a speed as to cause damage to the surroundings. Pyrotechnic substances are included even when they do not evolve gases.
2) A pyrotechnic substance is a substance or mixture of substances designed to produce an effect by heat, light, sound, gas, or smoke, or a combination of these as the result of nondetonative self-sustaining exothermic chemical reactions.
3) An explosive article is an article containing one or more explosive substances.

Class 1 is divided into six divisions and 13 compatibility groups.

Division 1.1. Substances and articles which have a mass explosion hazard (a mass explosion is one which affects almost the entire load virtually instantaneously).

Division 1.2. Substances and articles which have a projection hazard, but not a mass explosion hazard.

Division 1.3. Substances and articles which have a fire hazard and either a minor blast hazard or a minor projection hazard or both, but not a mass explosion hazard. This division comprises substances and articles: which give rise to considerable radiant heat; or which burn one after another, producing minor blast or projection effects, or both.

Division 1.4. Substances and articles which present no significant hazard. This division comprises substances and articles which present only a small hazard in the event of ignition or initiation during transport. The effects are largely confined to the package and no projection of fragments of appreciable size or range is to be expected. An external fire should not cause virtu-

ally instantaneous explosion of almost the entire contents of the package.

Division 1.5. Very insensitive substances which have a mass explosion hazard. This division comprises substances which have a mass hazard, but are so insensitive that there is very little probability if initiation or of transition from burning to detonation under normal conditions of transport. The probability of transition from burning to detonation is greater when large quantities are carried in a ship.

Division 1.6. Extremely insensitive articles which do not have a mass explosion hazard. This division comprises articles which contain only extremely insensitive detonating substances, and which demonstrate a negligible probability of accidental initiation or propagation; the risk is limited to the explosion of a single article.

Class 1 is unique in that the type of packaging frequently has a decisive effect on the hazard, and therefore on the assignment to a particular division. The correct division and compatibility group and the packaging are determined by the method outlined in Chapter 4 of the UN Recommendations.

The definition and the classification in divisions and compatibility groups of the UN Recommendations corresponded the those of IMO and RID/ADR.

3.1.2. Gases (Class 2)

UN Recommendations. A gas is a substance which:

1) At 50 °C has a vapor pressure > 300 kPa;
2) Is completely gaseous at 20 °C at a standard pressure of 101.3 kPa.

The transport condition of a gas is described according to its physical state as:

1) Compressed gas: a gas (other than in solution) which, when packaged under pressure for transport, is entirely gaseous at 20 °C;
2) Liquefied gas: a gas which when packaged for transport is partially liquid at 20 °C;
3) Refrigerated liquefied gas: a gas which when packaged for transport is partially liquid because of its low temperature; or
4) Gas in solution: compressed gas which when packaged for transport is dissolved in a solvent.

The class includes compressed gases, liquefied gases, gases in solution, refrigerated liquefied gases; mixtures of gases, mixtures of one or more gases with one or more vapors of substances from other classes, articles charged with a gas, tellurium hexafluoride, and aerosols.

Class 2 substances are assigned to one of three divisions based on the primary hazard during transport.

Division 2.1. Flammable gases. Gases which at 20 °C and a standard pressure of 10.3 kPa:

1) Are ignitable in a mixture of 13 vol % or less with air; or
2) Have a flammable range with air of at least 12 %, regardless of the lower flammability limit. Flammability should be determined by tests or by calculation in accordance with ISO 10 156: 1990 (where insufficient data are available, tests by a comparable method recognized by a national competent authority may be used).

Division 2.2. Non flammable, nontoxic gases. Gases which are transported at a pressure not less than 280 kPa at 20 °C, or as refrigerated liquids, and which:

1) Are asphyxiant gases, which dilute or replace the oxygen normally in the atmosphere; or
2) Are oxidizing gases, which may, generally by providing oxygen, cause or contribute to the combustion of other material more than air does; or
3) Do not come under the other divisions.

Division 2.3. Toxic gases. Gases which:

1) Are known to be so toxic or corrosive to humans as to pose a hazard to health; or
2) Are presumed to be toxic or corrosive to humans, because they have $LC_{50} \leq 5000$ mL/m^3 (ppm) when tested in accordance with Chapter 6 subparagraph 6.5 (c) of the Recommendations. Gases meeting the above criteria owing to their corrosive properties are classified as toxic with a subsidiary corrosive risk.

Mixtures of Gases. For the classification of gas mixtures into one of the three divisions (including vapors of substances from other classes) the principles of Chapter 1 of the UN Recommendations can be used.

Hazard Precedence. Gases and gas mixtures with hazards associated with more than one division take the following precedence:

1) Division 2.3 takes precedence over all other divisions
2) Division 2.1 takes precedence over Division 2.2

ADR/RID Definitions and Divisions of Class 2. Substances with critical temperature $< 50\,°C$, or at $50\,°C$, a vapor pressure greater than 300 kPa (3 bar) are deemed to be Class 2 substances. Substances and articles of Class 2 are classified as follows:

A) Compressed gases with critical temperature $< -10\,°C$
B) Liquefied gases with critical temperature $\geq -10\,°C$:
   a) Liquefied gases with critical temperature $\geq 70\,°C$
   b) Liquefied gases with critical temperature $\geq -10\,°C$, but $< 70\,°C$;C.
C) Deeply refrigerated liquefied gases
D) Gases dissolved under pressure
E) Aerosol dispensers and nonrefillable containers of gas under pressure
F) Gases subject to special requirements
G) Empty receptacles and empty tanks

The substances and articles of Class 2 are subdivided according to their chemical properties, as follows:

(a) Nonflammable
(at) Nonflammable, toxic
(b) Flammable
(bt) Flammable, toxic
(c) Chemically unstable
(ct) Chemically unstable, toxic

Unless otherwise specified, chemically unstable substances are considered to be flammable.

IMO Definitions and Divisions of Class 2 are the same as those in the UN Recommendations.

3.1.3. Flammable Liquids (Class 3)

UN Recommendations. Flammable liquids are liquids, or mixtures of liquids, or liquids containing solids in solution or suspension (paints, varnishes, lacquers, etc., but not including substances otherwise classified on account of their dangerous characteristics) which give off a flammable vapor at temperatures of not more than $60.5\,°C$ c.c., or not more than $65.6\,°C$ o.c., normally referred to as the flash point. However such liquids with a flash point of more than $35\,°C$, which do not sustain combustion need not be considered as flammable liquids for the purposes of the UN Recommendations. Liquids offered for transport at temperatures at or above their flash point are in any case considered as flammable liquids. Flammable liquids also include substances that are transported or offered for transport at elevated temperatures in a liquid state, and which give off a flammable vapor at or below the maximum transport temperature.

Liquids are considered to be noncombustible if they have passed a suitable combustibility test, if their fire point according to ISO 2592: 1973 is greater than $100\,°C$, or if they are water-miscible solutions with a water content of more than 90 wt %.

Viscous substances with flash point $< 23\,°C$ may be placed in Packing Group III. Substances classified as flammable liquids owing to their being transported or offered for transport at elevated temperatures are included in Packing Group III.

ADR/RID Definitions and Divisions of Class 3.

1) Flammable liquids within the meaning of ADR, are those that are liquid at the maximum temperature of $20\,°C$, or for viscous substances for which a specific melting point cannot be determined, and which are highly viscous according to the criteria of the penetrometer test (see Appendix A.3 of ADR and Appendix III of RID), or are liquid according to the ASTM D 4359-90 test method
2) Have at $50\,°C$ a vapor pressure ≤ 300 kPa (3 bar)
3) Have a flash point of $\leq 61\,°C$ c.c.

Class 3 substances, are assigned to one of the following groups designated (a), (b), or (c) according to their degree of danger:

(a) Very dangerous substances: flammable liquids with boiling point or initial boiling point not exceeding 35 °C, and flammable liquids with flash point < 23 °C which are either highly toxic according to the criteria of Class 6.1 or highly corrosive according to the criteria of Class 8
(b) Dangerous substances: flammable liquids with flash point < 23 °C which are not classified under (a), with the exception of viscous substances
(c) Substances presenting a minor danger: flammable liquids with flash point 23–61 °C, and some viscous substances

Methods used for grouping, and combustibility testing of flammable liquids as well as methods for grouping of flammable viscous substances with flash point < 23 °C can be found in Appendix A.3 of ADR and Appendix III of RID, respectively. Viscosity and flash point data are summarized in Table 1.

Table 1. Viscosity and flash point data of Class 3 substances

Kinematic viscosity ν (extrapolated), at near-zero shear rate at 23 °C, mm^2/s	Flow time t (ISO 2431-1984), s	Jet diameter, mm	Flash point, °C
20–80	20–60	4	>17
80–135	60–100	4	>10
135–220	20–32	6	> 5
220–300	32–44	6	>−1
300–700	44–100	6	>−5
>700	>100	6	≤ −5

IMO definitions and divisions of Class 3 are described in Section 3.1.

3.1.4. Flammable Solids, Substances Liable to Spontaneous Combustion, and Substances which in Contact with Water Emit Flammable Gases (Class 4)

UN Recommendations. Class 4 comprises:

Division 4.1. Flammable solids. Solids which, under conditions encountered in transport, are readily combustible or may cause or contribute to fire through friction; self-reactive and related substances which are liable to undergo a strongly exothermic reaction; desensitized explosives which may explode if not diluted sufficiently.

Division 4.1 comprises the following types of substances:

(a) Flammable solids
(b) Self-reactive and related substances
(c) Desensitized explosives

Division 4.2. Substances liable to spontaneous combustion under conditions encountered in transport, or to heating up in contact with air, and which are then liable to catch fire;

Division 4.2 comprises:

(a) Pyrophoric substances
(b) Self-heating substances

Division 4.3. Substances which in contact with water emit flammable gases. Substances which, by interaction with water, are liable to become spontaneously flammable or to give off flammable gases in dangerous quantities.

3.1.4.1. Flammable Solids [Division 4.1 (a)]

Properties. Flammable solids are readily combustible solids and solids which may cause fire through friction. Readily combustible solids are powders or granules, ignited by brief contact with an ignition source, such as a burning match, provided the flame spreads rapidly. The danger may come not only from the fire, but also from toxic combustion products. Metal powders are especially dangerous because of the difficulty of extinguishing a fire since normal extinguishing agents such as carbon dioxide or water can increase the hazard.

Classification of flammable solids should be carried out according to Chapter 14 of the UN Recommendations.

3.1.4.2. Self-Reactive and Related Substances [Division 4.1 (b)]

Definitions. Self-reactive substances are thermally unstable substances liable to undergo a strongly exothermic decomposition, even without participation of oxygen (air). Substances should be excluded from Division 4.1, if:

1) They are explosives, according to the criteria of Class 1

2) They are oxidizing substances, according to the assignment procedure of Division 5.1
3) They are organic peroxides, according to the criteria of Division 5.2
4) Their heat of decomposition is < 300 J/g
5) Their self-accelerating decomposition temperature (SADT) is $> 75\,^{\circ}$C for a 50-kg package

Heat of decomposition can be determined by any internationally recognized method, e.g., differential scanning calorimetry, adiabatic calorimetry. Any substance which shows the properties of a self-reactive substance should be classified as such, even if this substance gives a positive test result for inclusion in Division 4.2. Substances related to self-reactive substances are distinguished from the latter by having a self-accelerating decomposition temperature $> 75\,^{\circ}$C.

Properties. The decomposition of self-reactive substances can be initiated by heat, contact with catalytic impurities (e.g., acids, heavy-metal compounds, bases), friction, or impact. The rate of decomposition increases with temperature and varies with the substance. Decomposition, particularly if no ignition occurs, may result in the evolution of toxic gases or vapors. For certain self-reactive substances, the temperature should be controlled. Some self-reactive substances may decompose explosively, particularly if confined. This characteristic may be modified by the addition of diluents or by the use of appropriate packaging. Some self-reactive substances burn vigorously.

Self-reactive substances include: aliphatic azo compounds; organic azides; diazonium salts; *N*-nitroso compounds; aromatic sulfohydrazides.

Classification of self-reactive and related substances should be carried out according to Chapter 14 of the UN Recommendations.

Temperature Control Requirements. Self-reactive substances should be subject to temperature control if their self-accelerating decomposition temperature (SADT) is $\leq 55\,^{\circ}$C. Test methods for determining the SADT are given in the current edition of the Recommendations on the Transport of Dangerous Goods, Manual of Tests and Criteria. The test selected should be conducted in a manner which is representative, both in size and material, of the package to be transported.

3.1.4.3. Desensitized Explosives [Division 4.1 (c)]

Properties. Desensitized explosives are substances which are wetted with water or alcohol or diluted with other substances to suppress their explosive properties.

3.1.4.4. Substances Liable to Spontaneous Combustion [Division 4.2]

Properties. Self-heating of substances, leading to spontaneous combustion, is caused by reaction of the substance with oxygen (in the air), conduction of the heat developed not being rapid enough to avoid combustion. Spontaneous combustion occurs when the rate of heat production exceeds the rate of the heat loss and the autoignition temperature is reached. Two types of substance can be distinguished with spontaneous combustion properties:

(a) Substances, including mixtures and solutions (liquid or solid), which even in small quantities ignite within 5 min of coming into contact with air; these substances are the most liable to spontaneous combustion and are called pyrophoric substances.
(b) Other substances which in contact with air, without addition of energy, are liable to self-heating; these substances ignite only when present in large amounts (kilograms) and after long periods of time (hours or days), and are called self-heating substances.

Test methods for pyrophoric solids and liquids as well as for self-heating substances can be found in Chapter 14 of the UN Recommendations.

3.1.4.5. Substances which in Contact with Water Emit Flammable Gases (Division 4.3)

Properties. Certain substances in contact with water may emit flammable gases that can form explosive mixtures with air. Such mixtures

are easily ignited by all ordinary sources of ignition, e.g., naked lights, electrical sparts, or unprotected light bulbs. The resulting blast wave and flames may endanger people and the environment. A suitable test should be used to determine whether the reaction of a substance with water produces a dangerous amount of gases which may be flammable; it should not be applied to pyrophoric substances.

Methods of classification and assignment to packaging groups can be found in Chapter 14 of the UN Recommendations.

3.1.5. Oxidizing Substances and Organic Peroxides (Class 5)

UN Recommendations. This class comprises:

Division 5.1. Oxidizing substances which, while in themselves are not necessarily combustible, may, generally by yielding oxygen, cause, or contribute to, the combustion of other material.

Division 5.2. Organic peroxides which contain the bivalent – O – O – group and may be considered as hydrogen peroxide derivatives, with one or both of the hydrogen atoms replaced by organic radicals. Organic peroxides are thermally unstable substances, which may undergo exothermic self-accelerating decomposition.

Methods of classification and assignment to packaging groups can be found in Chapter 11 of the UN Recommendations.

Assignment of Organic Peroxides to Division 5.2. Any organic peroxide should be considered for classification in Division 5.2, unless the formulation contains:

1) Not more than 1.0 % available oxygen from the organic peroxides, when containing not more than 1.0 % hydrogen peroxide; or
2) Not more than 0.5 % available oxygen from the organic peroxides, when containing more than 1.0 %, but not more than 7.0 % hydrogen peroxide.

Allocation of new organic peroxides, or new formulations, or mixtures of currently assigned organic peroxides to a generic entry should be made by the competent authority of the country of origin, on the basis of a test report.

Methods for classification and assignment to packaging and packaging groups of organic peroxides can be found in Chapter 11 of the UN Recommendations. Suitable test methods with pertinent evaluation criteria are given in the current edition of Recommendations on the Transport of Dangerous Goods, Manual of Tests and Criteria, Part III.

Temperature Control. To avoid unnecessary confinement, metal packagings meeting the test criteria of Packing Group I should not be used. Organic peroxides are assigned to Packing Group II (medium danger).

3.1.6. Toxic and Infectious Substances (Class 6)

UN Recommendations. This class comprises:

Division 6.1. Toxic substances are liable either to cause death or to harm human health if swallowed, or inhaled, or by skin contact.

Division 6.2. Infectious substances contain viable microorganisms, including a bacterium, virus, Rickettsia, parasite, fungus, or a recombinant, hybrid or mutant, that are known or are reasonably believed to cause disease in animals or humans.

Genetically modified microorganisms and organisms which do not meet the definition of an infectious substance should be considered for classification in Class 9 and assignment to UN 3245.

Toxins from plant, animal, or bacterial sources which do not contain infectious substances or organisms, or which are not contained in them should be considered for classification in Division 6.1 and assignment to UN 3172.

3.1.6.1. Toxic Substances (Division 6.1)

Criteria for Defining Toxicity. Substances of Division 6.1, including pesticides, should be allocated among the three packing groups according to their degree of toxic hazard in transport as follows:

Packing Group I:	substances and preparations presenting a very severe toxicity risk
Packing Group II:	substances and preparations presenting a serious toxicity risk
Packing Group III:	substances and preparations presenting a relatively low toxicity risk

In making this grouping, account should be taken of experience in instances of accidental poisoning in humans, and of special properties possessed by any individual substance, such as liquid state, high volatility, any special likelihood of penetration, and special biological effects.

In the absence of human experience, grouping should be based on data obtained from animal experiments. Three possible routes of administration should be examined: oral ingestion; dermal contact; and inhalation of dust, mist, or vapor. Appropriate animal tests for the various routes of exposure are described in Chapter 6 of the UN Recommendations. When a substance exhibits a different order of toxicity by two or more of these routes of administration, the highest degree of danger indicated by the tests should be assigned.

The criteria for grouping a substance according to the toxicity it exhibits by all three routes of administration are presented in Chapter 6 of the UN Recommendations.

3.1.6.2. Infectious Substances (Division 6.2)

Infectious substances contain viable microorganisms: bacterium, virus, *Rickettsia*, parasite, fungus, or a recombinant, hybrid or mutant, that are known or reasonably believed to cause disease in animals or humans. However, they are not subject to the recommendations for this division if the spread of disease to humans or animals exposed to such substances is considered unlikely.

Infectious substances should be considered for classification in Division 6.2 and for assignment to UN 2814 (UN-No. 3245: genetically modified microorganisms) or UN 2900 after allocation to four risk groups, based on criteria developed by the World Health Organization.

Genetically modified microorganisms and organisms are microorganisms and organisms in which genetic material has been altered by genetic engineering.

Biological products are either finished biological products for human or veterinary use, manufactured in accordance with the requirements of national public health authorities, transported, if required, under special approval or license from such authorities; or biological products transported prior to licensing for development or investigation; or finished products for experimental treatment of humans or animals, manufactured in compliance with the requirements of national public health authorities. They also cover unfinished biological products, prepared in accordance with procedures of specialized government agencies.

Some licensed vaccines may present a biohazard in certain parts of the world only. In that case, competent authorities may require these vaccines to comply with the requirements for infectious substances, or may impose other restrictions.

Diagnostic specimens are any human material including, but not limited to, excreta, secreta, blood and its components, tissue and tissue fluids, transported for diagnostic or investigation purposes, but excluding live infected animals.

Wastes transported under UN 3291 (UN-No. 3291: clinical waste, unspecified, n.o.s. or (bio) medical waste, n.o.s. or regulated medical waste, n.o.s.) are wastes derived from the medical treatment of animals or humans or from bioresearch where there is a relatively low probability that infectious substances are present. Waste infectious substances which can be specified should be assigned to UN 2814 (UN-No. 2814: infectious substances, affecting humans) or to UN 2900 (UN-No. 2900: infectious substances, affecting animals only). Decontaminated wastes which previously contained infectious substances should be considered nondangerous, unless the criteria of another class are met.

These requirements are also applicable to RID/ADR and IMO from 1 January 1995.

3.1.7. Radioactive Material (Class 7)

UN Recommendations. A radioactive material is defined as any material with specific activity > 70 kBq/kg (0.002 μCi/g). In this context, specific activity means the activity per unit mass of radionuclide or, for a material in which the radionuclide is essentially uniformly distributed, the activity per unit mass of material.

Regulations regarding the transport of radioactive material have been prepared by the International Atomic Energy Agency (IAEA) in consultation with the United Nations, specialized agencies, and IAEA Member States.

3.1.8. Corrosive Substances (Class 8)

UN Recommendations. These are substances which, by chemical action, cause severe damage on contact with living tissue, or, in the case of leakage, materially damage, or even destroy, other goods or the means of transport; they may also cause other hazards.

Special Recommendations Relating to Class 8. Substances and preparations of Class 8 are divided among three packing groups, according to their degree of hazard in transport as follows:

Packing Group I:	very dangerous substances and preparations
Packing Group II:	substances and preparations presenting medium danger
Packing Group III:	substances and preparations presenting minor danger

Allocation of substances to the packing groups in Class 8 has been on the basis of experience, taking into account such additional factors as inhalation risk and reactivity with water (including the formation of dangerous decomposition products). [A substance or preparation meeting the criteria of Class 8 having an inhalation toxicity of dusts and mists (LC_{50}) in the range of Packing Group I, but toxicity through oral ingestion or dermal contact only in the range of Packing Group III or less, should be allocated to Class 8.] New substances, including mixtures, can be judged by the contact time necessary to produce full-thickness destruction of human skin. Substances judged not to cause full-thickness destruction of human skin should still be considered for their potential to cause corrosion of metal surfaces.

In making this grouping, account should be taken on experience in instances of accidental exposures to humans. In the absence of such experience grouping should be based on data obtained from animal experiments in accordance with OECD Guideline 404 [15].

The test criteria for the three groups in this class are:

Packing Group I (very dangerous substances): Substances that cause full-thickness destruction of intact skin tissue within an observation period of 60 min, starting after an exposure time of 3 min or less.

Packing Group II (substances presenting medium danger): Substances that cause full-thickness destruction of intact skin tissue within an observation period of 14 d, starting after an exposure time of more than 3 min, but not more than 60 min.

Packing Group III (substances presenting minor danger):

(a) Substances that cause full-thickness destruction of intact skin tissue within an observation period of 14 d, starting after an exposure time of more than 60 min, but not more than 4 h.
(b) Substances which are judged not to cause full-thickness destruction of intact skin tissue, but which exhibit a corrosion rate on steel or aluminum surfaces exceeding 6.25 mm/a at 55 °C. For the purposes of testing steel, type P 3 [ISO 2604 (IV): 1975] or a similar type, and for testing aluminum, non-clad types 7075-T 6 or AZ 5 GU-T 6 should be used.

3.1.9. Miscellaneous Dangerous Substances and Articles (Class 9)

UN Recommendations. These are substances and articles which during transport present a danger not covered by other classes, including substances that are transported or offered for transport at tempertures ≥ 100 °C in a liquid state or at temperatures ≥ 240 °C in a solid state.

IMO Definitions. Class 9 comprises:

1) Substances and articles not covered by other classes which experience has shown, or may show, to be of such a dangerous character that the provisions of part A Chapter VII of the International Convention for the Safety of Life at Sea, 1974, as amended, should apply
2) Substances not subject to the provisions of part A of Chapter VII of the aforementioned Convention, but to which the regulations of Annex III of the International Convention for the Prevention of Pollution from Ships, 1973, as modified by the Protocol of 1978 (MARPOL 73/78), apply

ADR/RID Definitions. Class 9 covers substances and articles which, during carriage, present a danger not covered by the headings of other classes; it includes:

Substances which, on inhalation as fine dust, may endanger health
Substances and apparatus which in the event of fire may form dioxins
Substances evolving flammable vapor
Lithium batteries

From 1 January 1995, a new subsection "Environmentally hazardous substances" should be implemented, including UN 3077 (Environmentally hazardous substances, solid, n.o.s.), and UN 3082 (Environmentally hazardous substances, liquid, n.o.s).

These UN numbers take into account inland water pollution effects as well as genetically modified microorganisms and organisms.

3.1.10. Estimation of Major Hazards when there are Several Hazardous Properties

Precedence of Hazard Characteristics of the UN Recommendations. Table 1.44 of the UN Recommendations may be used as a guide in determining the class of a substance, mixture, or solution having more than one risk, when it is not named in the list of dangerous goods in the UN Recommendations. For goods having multiple risks which are not specifically listed, the most stringent packing group assigned to the respective hazards of the goods takes precedence over other packing groups, irrespective of the precedence of the hazard table. The precedence of hazard characteristics of the following have not been dealt with in the table, as these primary characteristics always take precedence:

Class 1 substances and articles
Class 2 gases
Division 4.1 self-reactive and related substances and desensitized explosives
Division 4.2 pyrophoric substances
Division 5.2 substances
Division 6.1 substances with a Packing Group I inhalation toxicity, except for substances or preparations meeting the criteria of Class 8 having an inhalation toxicity of dusts and mists (LC_{50}) in the range of Packing Group I, but toxicity through oral ingestion or dermal contact only in the range of Packing Group III or less, which should be allocated to Class 8
Division 6.2 substances
Class 7 material

3.1.11. Seawater Pollutants and Inland Water Pollutants

In Germany, the individual federal states are responsible for regulating the transport of inland water pollutants, as reflected in the *Wasserhaushaltsgesetz* (WHG Paragraph 19 G). From 1 January 1995 the transport of inland water pollutants is regulated by the new section F of Class 9 marginals 11 and 12 ADR/RID.

Seawater Pollutants. At the International Conference of Marine Pollutants, 1973, the need was recognized to preserve the marine environment. Provisions are contained in Annex III of the *International Convention for the Prevention of Pollution from Ships, 1973*, as modified by the Protocol of 1978 (MARPOL 73/78). The Marine Environment Protection Committee, at its 21st session in 1985, decided that Annex III should be implemented through the International Maritime Dangerous Goods Code (IMDG-Code). This decision was endorsed by the Maritime Safety Committee at its 51st session in 1985.

Substances, materials, or articles are identified in the individual schedules of the IMDG-Code as Marine Pollutants. Substances, articles

or materials that are so identified, but do not possess any other hazard, are listed in the appendices to the schedules for UN 3077, or UN 3082, in Class 9.

Solutions, Mixtures, and Isomers. A solution or mixture containing $\geq 10\,\%$ of one or more Marine Pollutants is itself a Marine Pollutant.

Certain Marine Pollutants have an extreme pollution potential and are identified as Severe Marine Pollutants in the individual schedules. A solution or mixture containing 1 % or more of these Severe Marine Pollutants is a Marine Pollutant.

A solution or mixture which does not fall within the criteria of Classes 1 – 8, but which meets the criteria for Marine Pollutants should be offered for transport as an Environmentally Hazardous Substance, Solid, N.O.S, or as an Environmentally Hazardous Substance, Liquid, N.O.S, under Class 9, even though it is not listed by name.

An isomer of a substance identified as a Marine Pollutant and covered by a generic entry in Classes 1 – 8, but which does not fall within the criteria of these classes, should be offered for transport as an Environmentally Hazardous Substance, Solid, N.O.S, or as an Environmentally Hazardous Substance, Liquid, N.O.S, under Class 9, even though it is not listed by name.

Packages containing Marine Pollutants should be durably marked with the Marine Pollutant Mark; marking should not apply to:

1) Packages containing Marine Pollutants in inner packagings with contents of: 5 L or less for liquids; or 5 kg or less for solids
2) Packages containing Severe Marine Pollutants in inner packagings with contents of: 0.5 L or less liquids; or 500 g or less for solids

In the case of loss or likely loss overboard of marked Marine Pollutants into the sea, the master or other person in charge of the ship concerned must report the particulars of such loss or likely loss overboard, wherever it occurs, by the fastest telecommunication channel available with the highest possible priority to the nearest coastal state.

Inland Water Pollutants. In 1995 new requirements for the inclusion of Environmentally Hazardous Substances (Aquatic Pollutants) came into force. The criteria are consistent with the final text for substances pollutant to the aquatic environment adopted by the EC in Commission Directive No. 91/325/EEC, Section 5 [16].

In Appendix III/A.3 of RID/ADR a new Section G has been added test methods to determine the ecotoxicity, persistance and bioaccumulation of substances in the aquatic environment for classification in Class 9. The test methods used shall be those adopted by the OECD and EC. If other methods are used, they shall be internationally recognized, be equivalent to the OECD/EC tests and be referenced in the test report.

Tests to determine aquatic pollutant effects are as follows:

Acute toxicity for fish
Acute toxicity for *Daphnia*
Algal growth inhibition
Tests for bioaccumulation potential

3.2. Storage of Dangerous Goods

In Germany, the Technical Regulations for Dangerous Substances (*Technische Regeln für Gefahrstoffe*, TRGS) established by the Committee of Dangerous Substances (*Ausschuß für Gefahrstoffe* (AGS) reflect, albeit never definitively and completely, the state of regulations and knowledge mentioned in § 17 of the Directive of Dangerous Substances (*Gefahrstoff V*), especially for handling purposes. This also involves legal considerations of the storage of dangerous goods and substances.

The regulations to be applied are as follows:

- TRGS 511: storage of ammonium nitrate
- TRGS 514: storage of severely toxic and toxic substances in packaging and in portable tanks
- TRG 515: storage of oxidizing substances in packaging and in portable tanks

3.2.1. Explosive Substances (Class 1)

The storage of explosive substances is regulated by the Second Directive to the Explosive Law

(*2. SprengV*) in its latest edition of 5 September 1989, the Technical Regulation for the Storage of Explosives, which are subject to 2. SprengV and the section on Accident Prevention Regulation (*Unfallverhütungsvorschrift*, UVV) 46 a *Explosive Substances and Articles with Explosive Substances*, General rule (VBG 55 a) established by the Employers' Liability Insurance Association of Chemical Industries (*Berufsgenossenschaft der chemischen Industrie*). In 2. SprengV in §1, item (2), No. 1 and 2, the area of application is clearly described. The Directive is not applicable to explosive substances during transportation by road, rail, water, or air, and on vehicles mentioned in § 1, item (2), No. 1 and during loading or unloading.

Storage Groups. Explosives and explosive articles are classified in four storage groups, by analogy to the transport Divisions 1.1 – 1.4. There are no storage groups corresponding to Divisions 1.5 and 1.6.

The assignment of substances and articles to storage groups is normally based on results of tests which are carried out by the Federal Institute for Materials Research and Testing (BAM). These tests and the criteria for the assignment to storage groups are described in the Rules for the Storage of Explosives (*Sprengstofflagerrichtlinie*, Spreng LR 010). Of most importance are the properties of the substances and articles in their packagings, in connection with their degree of risk to the public. Explosive substances from the chemical industry are also covered by the German Explosives Law, but for transportation purposes are normally placed in classes other than Class 1 (e.g., Classes 4.1 or 5.2). Such explosive chemicals are also assigned to certain storage groups on the basis of experimental procedures described the Spreng LR 011.

Compatibility Groups. According to certain properties of the substances or articles, a compatibility group is determined (A, B, C, D, E, F, or G). The definitions of the compatibility groups correspond to those used for transport.

3.2.2. Flammable Liquids (Class 3)

For storage of flammable liquids in Germany specific Technical Regulations (*Technische Regeln für brennbare Flüssigkeiten*, TRbF) are valid. Their objective, as part of the according Directive (*Verordnung über brennbare Flüssigkeiten*, VbF), is to regulate filling, loading, and unloading of flammable liquids.

The regulations are divided as follows:

- TRbF 001: general provisions, structure, and applicability
- TRbF 002: standards, etc.
- TRbF 003: testing of flammable liquids
- TRbF 100/200: general safety requirements
- TRbF 111/211: places of filling, emptying
- TRbF 120/220: general provisions for metallic or nonmetallic fixed tanks
- TRbF 121/221: specific provisions for metallic or nonmetallic fixed tanks

According to the VbF, flammable liquids are those which are liquid or viscous at a temperature not exceeding 35 °C and which have vapor pressure not exceeding 300 kPa (3 bar) at a temperature of 50 °C.

3.2.3. Oxidizing Substances (Class 5.1)

The storage of oxidizing substances in packaging and in portable tanks should be in accordance with the provisions of the technical rule TRGS 515. This rule is not valid for substances in process, handling, storage under the provision for the transport of dangerous goods, and amounts of substances stored up to 200 kg. From 1 October 1993, the storage and handling of organic peroxides is regulated by a new Accident Prevention Regulation (VBG 58) published by the Employer's Liability Insurance Association of Chemical Industries Peroxides are assigned, according to their danger, to storage groups, similar to those for explosive substances.

3.2.4. Toxic Substances (Class 6.1)

The storage of toxic substances in packaging and in portable tanks should be in accordance with the provisions of the technical rule TRGS 514. This rule is not valid for substances in process, handling, storage under the provision for the transport of dangerous goods, and amounts of substances stored up to 200 kg (50 kg for very toxic substances).

3.2.5. Radioactive Material (Class 7)

Within the nuclear fuel cycle, the safe storage of different types of radioactive material is necessary. An important product for nuclear fuel fabrication is uraniumhexafluoride UF_6 which is shipped and stored in steel cylinders designed to withstand a test pressure of 2.8 MPa (28 bar).

Spent nuclear fuel must be stored after removal from the reactor, first in water ponds within the nuclear power plant. This first stage of storage (when most of the decay heat is dissipated) is followed by reprocessing or interim storage for a longer period, up to 50 years. There are several interim storage options for spent fuel or high-level waste:

- Dry storage in an inert gas atmosphere in casks, silos, or vaults
- Wet storage in water ponds

In every case, the technical measures have to satisfy the following protection aims:

Shielding against radiation
Containment of the radioactive inventory
Nuclear safety
Heat removal

The back-end of the nuclear fuel cycle is the disposal of the radioactive waste products, or the direct disposal of spent nuclear fuel.

In some countries, low-level or non-heat-generating waste is disposed of in above-ground repositories (United States, France); in other countries in deep underground repositories (Sweden, Germany). High-level waste or spent fuel should be disposed of only in deep geological formations. The general safety principles for the disposal of radioactive materials are:

- Immobilization of radioactive isotopes (e.g., by vitrification, cementation)
- Containment by technical and geotechnical barriers during the service period of the repository
- Long-term containment by geological barriers

4. Safety Measures

To minimize the risk in transportation, handling, and storage of hazardous substances appropriate safety measures must:

1) Assure safe service conditions
2) Reduce the probability of incidents or accidents
3) Reduce the consequences of accidental release

Safety measures can be classified as:

1) Measures to assure safe confinement of the hazardous substance during normal service conditions, abnormal service conditions (incidents), and accidents (i.e., accident prevention measures)
2) Measures to reduce the consequences of accidental losses (i.e., accident limitation measures)

Besides this "horizontal" differentiation, a "vertical" division of safety measures into:

Technical safety measures
Operational safety measures

is possible. Table 2 shows the combination of the main components of safety measures. To ensure that all measures are met effectively and within specified limits, qualitiy assurance is necessary, at every stage.

The most interesting problem in safety science and technology is the correct choice (i.e., the selection of the appropriate combination and technical level) of measures to provide a level of safety, accepted on commercial considerations by the supplier, on safety grounds by the workers, and on environmental aspects by the public. Figure 1 shows the correlation between incident probability and consequences. If the specific hazard potential of substance 2 (case 2) is bigger than that of substance 1 (case 1), only a lower "consequence grade" (e.g., a lower release rate) in case of an accident can be accepted; the consequences for substance 2 have to be restricted to the site area, but for substance 1 an accident consequence may be accepted outside. With respect to the safety measures necessary to reduce the incident probability to an acceptable level, the minimum safety in case 2 has to be higher than in case 1.

Table 2. Combination of the main components of safety measures

Safety measures	Normal service safety measures	Accident prevention measures	Accident limitation measures
Technical measures	design of containment and service equipment according to normal conditions	accident-safe design with special equipment (e.g., double containment, fire protection, alarms, shut-down) special provisions (e.g., fail-safe, fire-safe, redundancy, diversity)	separation, size limitation, safety distance, hold-back measures
		marking, labeling	
Operational measures	experience, training		
	handling and testing instructions, maintenance		emergency response, recovery action
Quality assurance measures			

Figure 1. Correlation between incident probability, consequences, and safety level for two cases of acceptable hazard

4.1. Technical Safety Measures

Technical safety measures have to assure safe service conditions or (if they are so designed) safety in accidents. The design of a technical system has to consider the right configuration of "function units" with components made from suitable materials, correctly dimensioned, and equipped with all necessary devices. The design or construction process has to consider all relevant design loads:

Design load
Mechanical impacts
Pressure
- internal and/or external over-pressure
- design pressure
- working pressure
- test pressure
- hydrostatic pressure
- pump pressure

Vibration
Operational loads
Wind, snow floods
Accident impact
- drop
- crush
- puncture
- ripping
- missile

Thermal impact
Substance temperature
Ambient temperature
Fire
- torch fire
- full engulfment
- partial engulfment
- radiation from external fire

Corrosion
Substance
Environment
Time-induced effects
Aging
Creep
Stress relaxation

Construction/design features
Purpose
Lifetime
Materials
Dimensions
Equipment
Configuration of units and components
Safety principles
- safety level
- single or multiple barriers

redundancy
diversity
fail-safe design
fire-safe design

The following examples illustrate the interdependance of design features, design loads, and purpose.

4.1.1. Design and Equipment of Tanks and Packages

Transport and storage containers exceeding a capacity of 3 m^3 are usually designed as pressure vessels. Commonly, calculation of the resistance to internal over-pressure is based on the maximum vapor pressure of the dangerous substance under service conditions; this pressure depends on the kind of substance and the reference temperature of the vapor pressure. The vessel's resistance to internal over-pressure is determined by the wall thickness and the maximum allowable shell stress value, i.e., a specified proportion of the yield or tensile strength of the tank material. The ratio of strength to allowable stress is the safety factor: the material's ability to withstand mechanical impacts should only be consumed partially under normal service conditions, leaving a reserve in the case of accidents. The calculation of the minimum shell thickness for a cylindrical pressure vessel is given by:

$$s = \frac{D_a p}{20 \frac{K}{S} v + p} + c_1 + c_2$$

with s = minimum tank shell thickness (mm); p = design pressure (bar = 100 kPa); D_a = external diameter of the cylindrical tank shell (mm); K = material strength at design temperature (N/mm^2); S = safety coefficient at design pressure; v = "weld coefficient", representing the absorption of the allowable design stress in a welded joint (v = 1 if a 100 % nondestructive test of the welded joint is required); c_1 = allowable tolerances of the tank shell material's dimensional standards; and c_2 = possible effects of corrosion.

Other components of a pressure vessel (heads, manholes, flanges, pipes, valves, etc.) are designed according to similar calculations.

The whole vessel and piping design, including calculation, material selection, equipment, manufacturing, and testing must be carried out according to an accepted pressure vessel design code, e.g., ASME [17], or *AD-Merkblätter* [18].

The safety level expressed by these codes is adequate only up to the pressure hazard potential, usually expressed as the product of pressure and volume. For a given material, the wall thickness may be taken as indication for the safety level of a pressure vessel; every parameter determining this wall thickness (for a given design pressure) depends on the type of vessel material. These parameters have been established on the basis of experience for the most common structural materials, and are defined in the codes. For example, Table 3 shows safety coefficients for some ductile metals; interpretation of these data yields some valuable safety principles:

1) The better the ductility of the material, the lower the safety coefficient to be applied (plastification before fracture can give significant energy absorption before rupture of the vessel)
2) Vessels of forged or rolled steels and aluminum alloys, i.e., metals with reasonably high ductility, are stressed at the final inspection, and in reinspection tests, at a test pressure 1.3 times the maximum allowable working pressure (MAWP); the tank shell is stressed up to 90 % of the material's strength, usually the yield strength
3) Vessels of metals with limited ductility (e.g., cast iron) have to withstand a test pressure which is twice the MAWP

An additional possibility to influence the safety level via the tank shell thickness is the determination of the design pressure of the tank. Usually, the design pressure is the maximum over-pressure that may occur during operation. For liquids of low vapor pressure, the MAWP may be mainly determined by the filling pump pressure; for high vapor pressures (e.g., in transportation and storage of gases) the design pressure is the vapor pressure at the maximum operational temperature. These "reference temperatures", together with the relations between MAWP and test pressure, and the definitions of the maximum allowable stresses for different modes of transport and for storage are given in Figure 2.

Table 3. Safety coefficients for ductile metals

Material	Safety coefficient S at design temperature and maximum working pressure	Safety coefficient S' at test pressure
Forged and rolled steels	1.5	1.1
Cast steels	2.0	1.5
Ductile cast iron (DIN 1693)		
GGG 60/70	5.0	2.5
GGG 50	4.0	2.0
GGG 40	3.5	1.7
GGG 40.3 (with guaranteed toughness)	2.4	1.2
Aluminum and Al alloys	1.5	1.1

For the same tank size and material, calculation for a pressure-liquified gas such as propane shows that a road transportation tank with sun protection has to be designed with a shell 1.33 times thicker than that of an above-ground storage vessel. Transportation regulations generally have to consider a higher probability of accidents impacting the tank from the outside, e.g., in crashes. For hazardous liquids, this is achieved by setting minimum shell thickness standards or "fictive" high design pressures, to design a tank that is more resistant to external forces.

According to the specific hazard potential of substances, land transportation regulations (RID/ADR) require tank shell thicknesses based on "fictive" design over-pressure steps of 0.4, 1, 1.5, and 2.1 MPa; sea transportation regulations (IMGD-Code) require minimum shell thickness values of 6, 8, 10, or 12 mm (mild steel, tank diameter > 1.8 m). These regulatory shell thickness requirements qualitatively enhance tank safety, but only in a very general manner, and do not consider quantitatively safety against external impact. Attempts to increase the safety of tanks by technical measures and material selection are made in risk assessment studies [19, 20], or by investigations of the global or local resistance of tanks or tank components to accidental mechanical forces [21, 22].

The safety of packagings and intermediate bulk containers (IBC) has to be proved mainly by performance tests. According to the UN Test Requirements for Packagings (with the exceptions of Class 2 and Class 7 substances) the following tests have to be carried out on every design type:

Drop Test. The number of test samples and the drop orientations depend on the kind of packaging; the packaging must be dropped onto a rigid, nonresilient, flat, horizontal target. The drop height depends on the packing group (PG) of the substance, i.e; the specific hazard potential: 1.8 m for PG I, 1.2 m for PG II, and 0.8 m for PG III.

Leakproofness test at an air pressure not less than 30 kPa (PG I) or not less than 20 kPa (PG II, III).

Internal pressure (hydraulic) test at a test pressure of 250 kPa (PG I) or not less than 1.5 times the vapor pressure at 55 °C (minus 10 kPa), but at least 10 kPa (PG II, III).

Stacking test with minimum stacking height of 3 m.

A very special case is the set of performance test criteria for so- called type-B packages for radioactive materials. These criteria include tests of the ability to withstand severe accident conditions in transport. A package sample is subjected to the cumulative effects of mechanical tests (9 m drop onto an unyielding target, 1 m drop onto a steel bar, and a crush test by a 500 kg mass dropped from a height of 9 m) as well as a thermal test (30 min full fire engulfment, e.g., in a kerosene pool fire with flame temperatures exceeding 800 °C). An additional requirement is a water immersion test (150 kPa external gauge pressure of 2 MPa for packages with a radioactive inventory exceeding a specified limit). These severe performance tests, after which a specified activity release rate has to be guaranteed, lead to a package design that is safe, even under the worst accident conditions.

4.1.2. Fire Protection Measures

The biggest losses in industrial sites are often caused by fires. Storage sites or tanks with large amounts of hazardous materials have to be carefully fire protected. The usual classification is:

"Passive" fire protection measures, such as buildings, building components, insulation layers, and coatings resistant over a specified duration to a specified fire scenario, e.g., a furnace test fire [23]

Figure 2. Pressure design criteria for gas tanks
(∗) Set pressure of the pressure-relief device.

"Active" fire protection measures, such as fire extinguishing systems, sprinkler and water spray systems

For effective fire protection of dangerous goods tanks, and for fire fighting in sites where the tanks are on fire or close to it understanding the behavior of tanks engulfed by a fire is essential. For LPG tanks Figure 3 shows the relation between fire duration and vessel-bursting pressure (upper curves), and the internal over pressure (lower curves). If the tank is equipped with a pressure-relief valve, and protected by an effective coating, which may be a layer of insulation, intumescent or subliming material [24], the internal over-pressure is always well below the bursting pressure. An unprotected tank, although equipped with a high- capacity pressure-relief device, will burst after a reasonably short fire duration if the tank is fully engulfed. If the tank is only partially engulfed this will happen just as fast if the fire engulfs the tank shell in the vapor space, where the shell is heated very rapidly; the shell wetted by the liquid is not heated so rapidly because of efficient heat transfer to the liquid. Figure 3 also shows cases where the tank has little or no pressure-relief apparatus; vessel bursting may occur very rapidly, in the case of LPGs leading to a boiling liquid expanding vapor explosion (BLEVE) with desastrous consequences for the environment (tank fragmentation, fire-ball heat radiation, and explosion overpressure).

Fire extinguishing systems, commonly used in closed-storage facilities, put the storage space under inert gas (e.g., CO_2) or foam to extinguish a fire. Sprinkler and water spray systems oper-

Figure 3. Liquefied petroleum gas (LPG) tank behavior in a fire
△ = BLEVE (boiling liquid expanding vapor explosion)

ate by cooling. All these systems have to be initiated, usually automatically by fire detectors; their reliability depends on the proper functioning of many components, and their full efficiency is reached only after a lag time. Therefore, inherently safe fire protection measures, e.g., a fire-resistant construction, is often preferred for sites with major risks. Details of fire protection methods can be found in industrial handbooks e.g., [25, 26].

4.2. Quality Assurance Measures

Quality assurance (QA) programs should be established for the design, manufacture, testing, documentation, use, maintanance, inspection, transport, handling, and storage operations ofall containments for dangerous goods to ensure compliance with the relevant safety regulations and the provisions of approval certificates. In this context, "quality" is the compliance of a tank or package at any stage of its lifetime with the regulations, so that an approved safe condition is achieved.

For a package, a brief survey of QA is shown in Figure 4.

Quality assurance is based on a quality policy, quality management (within all institutions that design, manufacture, operate, test, examine, inspect, or approve), and a system of quality controls and audits.

Basic ISO QA standards (with comparable European standards) are given in:

– ISO 9000 (EN 29 000) Quality Management and Quality Assurance Standards – Guidelines for Selection and Use
– ISO 9001 (EN 29 001) Qualitiy Systems – Model for Quality Assurance in Design/Development, Production, Installation and Servicing
– ISO 9002 (EN 29 002) Qualitiy Systems – Model for Quality Assurance in Production and Installation
– ISO 9003 (EN 29 003) Quality System – Model for Quality Assurance in Final Inspection and Test
– ISO 9004 (EN 29 004) Quality Management and Quality System Elements – Guidelines

Quality can be produced only by skilled engineering, manufacture, and operation, by well-educated and trained personnel. A very sophisticated QA program is able to filter out failures only to a certain extent.

4.3. Safety Distances

Accidental release should be prevented by technical and operational safety measures as described above, but within a safety analysis for

Phase	Item		Quality assurance tasks	Quality assurance instruments
Design control and approval		Test object	Quality control of: test object properties test parameters	Test program, test records, examination and documentation of test object properties, test report
		Package design	Validation of design safety evaluation, considering: transferability of the test results, assessment of quality standards	Safety evaluation report, including design specifications (drawings, specifications of materials and components)
Manufacture		Package produced	Assessment of fabrication and test procedures Quality control to assure design specifications Evaluation of deviations from specification	Quality assurance program QA manual fabrication and inspection plans including: fabrication instructions test instructions responsibility of inspectors/experts according to a classification system final inspection plan QA records
Operation			Maintenance, safe operation, and quality control to assure design specifications	Operation and inspection plan Maintenance and reinspection test instructions } Transport Acceptance test criteria Storage manual } Storage

Figure 4. Quality assurance

any site where a major risk exists, the consequences of a potential hazardous material release have to be determined.

Estimation of consequences may be necessary for the planning of emergency response action, as well as for plant construction or storage size limitation to provide appropriate distances between the hazard source and other plant areas (storage spacing) or public facilities. First, a realistic accident scenario has to be considered to derive a source term (instantaneous release of a certain amount of dangerous goods, or a specified continuous release rate). Depending on the behavior of the substance in mind, the subsequent reaction may be ignition, explosion, release of hazardous reaction products, or dispersion only. Depending on the substance-specific hazard potential (specific toxicity, flammability, explosibility, causticity, radioactivity, etc.), and other influences (e.g., metereologic and plant conditions) the hazard spreads, up to a certain distance. The distance up to which the hazard is at an unacceptable level, e.g., 50 % lethal dose toxicity (LD_{50}), or heat radiation or explosion over-pressure causing severe injury or building damage is termed the "safety distance."

The effects of the release of flammable liquids and gases (heat flux, over-pressure and tank missile flight after a BLEVE, vapor cloud explosion, or fire) can be estimated from formulae in the appropriate guides and handbooks, e.g., [28, 30]. Somewhat more difficult is the calculation of gas dispersion to estimate, e.g., the lower flammability distance in LPG releases or toxic concentration distances (e.g., for ammonia or chlorine releases) because of the effects of metereologic circumstances; calculation standards for these are also available [31].

If the existing safety distance is less than an estimated unacceptable hazard distance, additional safety measures have to be taken. These may be either source-term-reducing measures, such as smaller vessels, thinner or shorter pipes between shut-off valves, or hazard-distance-reducing measures, such as gas-tight walls or confinements, or water curtains to reduce the gas concentration.

4.4. Emergency Response

Emergency response action is necessary as a back-up, to limit the consequences of an accidental release of hazardous substances in case of a failure of all technical barriers. The correct and durable marking, labeling, and placarding of dangerous goods containments is the first important measure for corrective action. Transport media for dangerous goods must carry additional labels or instructions identifying the primary and subsidiary risks of the substance, and indications of the initial emergency response. More details are necessary for the fire fighters at the accident site. Some countries have set up special task-forces with appropriate equipment for dangerous goods transport accidents; these task-forces can get additional support from quick-response hazardous substances data banks from specialist advisers, or from technical equipment supplied by the chemical industry. Support is organized either on a national basis, e.g., in Germany by TUIS, a transportation accident information and emergency response system run by the chemical industry [32], or internationally, e.g., in Europe by ICE run by the European Chemical Industry Council, CEFIC [33]. For major-risk storage sites, a detailed alarm and emergeny response plan that regulates all necessary action inside the plant, and the activation of external help by local authorities and fire fighters must be approved and regularly up-dated during operation.

5. Regulations and Standards

5.1. World Transport Regulations

The purpose of all regulations for the transport of dangerous goods is to minimize the associated risks, while limiting the costs for the industry concerned to an acceptable level.

The basis of all regulations is a classification system for dangerous goods by type of hazard and degree of danger.

According to the predominant hazard of the dangerous substance, classification is the same for all regulations for the transport of dangerous goods:

Class 1	Explosives
Class 2	Gases
Class 3	Flammable liquids
Class 4.1	Flammable solids
Class 4.2	Substances liable to spontaneous combustion
Class 4.3	Substances which in contact with water emit flammable gases
Class 5.1	Oxidizing substances
Class 5.2	Organic peroxides
Class 6.1	Toxic substances
Class 7	Radioactive material
Class 8	Corrosive substances
Class 9	Miscellaneous dangerous substances

About 2500 individual substances and articles have been classified; substances, not specifically listed in the regulations, but which are dangerous according to the criteria, have to be classified, to be acceptable for carriage under the same conditions as substances presenting a comparable hazard. Some substances are too dangerous for transport, and may be carried only in a stabilized form or in solutions or mixtures. All regulations specify the conditions of carriage for the dangerous substances, such as:

Conditions of packing
Marking and danger labels on packages
Information in the transport document
Conditions for tank transport
Mixed loading and segregation
Special conditions for different modes of transport

5.1.1. UN Recommendations on the Transport of Dangerous Goods

Since 1956 a Committee of Experts on the Transport of Dangerous Goods established by the United Nations Economic and Social Council has been developing Recommendations on the Transport of Dangerous Goods [34]: Although the UN Recommendations have no legal force, they aim at presenting a basic scheme to allow international regulations for the various modes of transport to develop in a uniform fashion.

All bodies responsible for the international regulations have committed themselves to harmonize their regulations as far as possible with the principles of the UN Recommendations.

The most important part of the Recommendations is the *List of Dangerous Goods Most Commonly Carried*. A four-digit number is assigned

in the list to each substance or article. Unfortunately, this UN number gives no information about the hazards of the substance or article.

Classification of dangerous substances not individually listed in the Recommendations is possible under a great number of "generic" or "not otherwise specified" (N.O.S.) entries. Such classifications should be based on the results of tests, and on experience [35].

The UN Recommendations also cover provisions for packing, multimodal tank transport, consignment procedures, marking, and labeling.

The Committee of Experts gives no recommendations for the transport of radioactive materials. In 1959, the UN Economic and Social Council asked the International Atomic Energy Agency (IAEA) to prepare Regulations for the Safe Transport of Radioactive Material [36]. These Regulations, which are referred to in the UN Recommendations, have been introduced in all international regulations for the transport of dangerous goods.

5.1.2. The IMDG-Code

The International Maritime Organization in London has prepared requirements for the safe transport of dangerous goods by sea. These requirements were originally based on the *International Convention for the Safety of Life at Sea* (SOLAS) of 1960. To prevent marine pollution by the transport of dangerous substances, the requirements also include provisions based on the *International Convention for the Prevention of Pollution from Ships* (MARPOL) of 1973.

The requirements are laid down in the *International Maritime Dangerous Goods Code* (IMDG-Code, [37]). The IMDG-Code is recommended to governments for adoption as the basis for national regulations in pursuance of their obligations under the SOLAS Convention.

The IMDG-Code follows very closely the UN Recommendations with regard to the classification, packing, and tank transport of dangerous goods.

A special feature of the IMDG-Code is the presentation of provisions for packing: an individual page for each substance or entry makes the IMDG-Code the most voluminous of all international regulations for the transport of dangerous goods.

In addition to the provisions in accordance with the UN Recommendations, the IMDG-Code sets out special requirements for the transport of dangerous goods in ships, such as:

Provisions for freight container traffic
Stowage and segregation of dangerous goods on ships
Fire precautions
Dangerous goods on roll-on, roll-off ships
Transport of solid bulk materials.

Furthermore, a supplement to the IMDG-Code includes publications of the International Maritime Organization relating to the IMDG-Code, such as:

The Emergency Procedures for Ships carrying Dangerous Goods (EmS)
The Medical First Aid Guide (MFAG)
The Code of Safe Practice for Solid Bulk Cargoes
Reporting procedures
The Guidelines for Packing Cargo Transport Units
Recommendations on the use of pesticides in ships.

5.1.3. The ICAO Technical Instructions

The International Civil Aviation Organization in Montreal is responsible for regulating the air transport of dangerous goods. In 1984, the first edition of the ICAO *Technical Instructions for the Safe Transport of Dangerous Goods by Air* [38], based on Annex 18 to the Convention on International Civil Aviation was introduced. Before then, the transport of dangerous goods by air had been regulated by the International Air Transport Association (IATA), also in Montreal in the IATA Restricted Articles Regulations.

The ICAO Technical Instructions are also fully harmonized with the UN Recommendations as regards the classification and the provisions for packing, labeling, and documentation.

There are, however, many restrictions on air transport: many substances and articles from the UN Recommendations, e.g., explosives, are forbidden for air transport, and there are many restrictions on the net quantity per package. Restrictions are more severe for passenger than for cargo aircraft.

Most of the conditions of carriage in the ICAO Technical Instructions are included in the alphabetical Table of Dangerous Goods, which also refers to packing instructions and special provisions.

In addition to the provisions in accordance with the UN Recommendations, the ICAO Technical Instructions cover special requirements for air transport, such as:

Provisions for magnetized material
Loading of dangerous goods on aircraft
Information to flight crews
Training of shippers and operators and all other persons handling dangerous air cargo
Variations of the Technical Instructions, notified by states and airline operators.

5.2. Regional Transport Regulations

5.2.1. Europe

The first regulations for international transport of dangerous goods in Europe were developed over 100 years ago for rail transport. Regulations for road transport and transport by inland waterway were developed after World War II, and are all based on the regulations for rail transport (RID). Considerable effort has been made to harmonize all European regulations on aspects such as classification, packing, labeling, and marking as well as the requirements for tank wagons, tank containers, and tank vehicles.

All European regulations are being harmonized with the UN Recommendations. This is difficult, because there are still fundamental differences in safety principles underlying the UN Recommendations and the European regulations.

The Regulations Concerning the International Carriage of Dangerous Goods by Rail (RID). The RID (*Règlement Concernant le Transport International Ferroviaire des Marchandises Dangereuses* [39]) is Annex I to the International Convention concerning the Carriage of Goods by Rail (CIM). The RID is applicable to transport between most European countries and some countries of northern Africa and the Middle East, i.e., the Member States of the Intergovernmental Organization for the International Carriage by Rail (OTIF), based in Bern.

The first regulations for the transport of dangerous goods by rail came into force in 1893. Development of the regulations is the responsibility of the RID Safety Committee, which works closely with road transport experts in the joint RID/ADR Meeting.

Although the criteria for classification of dangerous goods in RID are harmonized with the UN Recommendations, there is a special feature in RID and other European regulations. The conditions for carriage are set out for the substances of each class separately, starting with a systematical list of substances and articles; all substances and articles are grouped under collective headings according to their physical and chemical properties and their degrees of hazard. The appropriate N.O.S. entry from the UN Recommendations concludes every group of substances under the collective heading, to accommodate classification of new substances and articles. This classification system ensures that the same conditions of carriage apply to substances under one collective heading or item; the format of the regulations can be kept simple, without the need for amendment of the regulations for every new substance.

The conditions of carriage in each class cover the following subjects:

– Conditions of packing, including marking and labeling
– Particulars in the consignment note
– Conditions for wagons and loading, including marking and labeling

The RID also includes appendices with provisions for testing substances, packaging (including intermediate bulk containers), for radioactive material, and provisions for tank containers and tank wagons.

The European Agreement Concerning the International Carriage of Dangerous Goods by Road (ADR). The ADR (*Accord Européen Relatif au Transport International des Marchandises Dangereuses par Route* [40]) was concluded in 1957. Most European states are contracting parties to the ADR. Development of the ADR is the responsibility of a Working Party, established by the Inland Transport Committee of

the United Nations Economic and Social Council.

Annexes A and B cover the same subjects as RID. Annex B also covers some provisions important for road transport, such as:

Technical equipment of road vehicles

General service requirements, driver training

Provisions concerning loading, unloading, and handling

Provisions concerning the operation of vehicles

The European Provisions Concerning the International Carriage of Dangerous Goods by Inland Waterway (ADN). It is the intention of the UN Economic Commission for Europe to additionally put into force an agreement for the transport of dangerous goods by inland waterways. At present the ADN exists only in the form of a draft.

The Regulations for the Carriage of Dangerous Goods on the Rhine (ADNR). The ADNR (ADN-Rhine) is based on the existing drafts for the ADN and has been developed by the Central Commission for the Navigation on the Rhine in Strasbourg. The plan is for the ADNR to be subsumed by the ADN.

For the transport of packaged goods, the ADNR refers to other regulations for the transport of dangerous goods; it mainly regulates the transport of dangerous goods in bulk, and therefore consists of provisions for the construction, equipment, and operation of vessels.

Directives of the European Communities with Regard to the Transport of Dangerous Goods. It is the intention of the Commission of the European Communities to extend the implementation of the existing international regulations for the transport of dangerous goods to national transport in the Member States of the Community.

5.2.2. United States

The transport of dangerous goods (called hazardous materials in the United States) is subject to Title 49 of the United States Code of Federal Regulations Parts 107 – 180 (49 CFR Parts 107 – 180), except that bulk transport in tank ships and tank barges on the navigable waters of the United States is covered by other regulations. The Associate Administrator for Hazardous Materials Safety of the Research and Special Programs Administration (RSPA) is responsible for maintaining the regulations and is also the United States competent authority for purposes of the ICAO Technical Instructions on the Safe Transport of Dangerous Goods by Air and the IMDG-Code.

In many respects the contents of the United States Hazardous Materials Regulations (HMR) are similar to the international requirements for dangerous goods transport contained in the ICAO TI and the IMDG-Code. This is largely the result of amendments made to 49 CFR in December 1990 and 1994. These amendments substantially aligned United States requirements for classification, transport documents, nonbulk packaging, labeling, package marking, and placarding with the UN Recommendations on the Transport of Dangerous Goods. In addition, the HMR also include vehicle construction and operating requirements for transporting hazardous materials by rail and highway, operating requirements for transporting hazardous materials by air, and the procedures under which an exemption to the regulations may be obtained.

In the case of consignments by air or water, two provisions in the Regulations are particularly important. Subject to specified conditions, 49 CFR 171.11 authorizes transport of hazardous materials on aircraft and any associated highway transport in accordance with the ICAO Technical Instructions. Similarly, 49 CFR 171.12 authorizes transport of hazardous materials by ship and any associated land transport in accordance with the IMDG-Code if part of the transport of the material involves transport by water. A number of exceptions apply to transport in accordance with the ICAO and IMO requirements and the reader is advised to consider these provisions which are identified in 49 CFR 171.11 and 171.12. Some of the more important conditions include:

Environmentally hazardous substances are identified in the Regulations and must be transported under UN 3077 or UN 3082 if they do not meet the criteria of hazard Classes 1 – 8, and special hazard communication requirements apply to environmentally hazardous substances identified in the regulations.

Transport of hazardous materials in portable tanks is subject to 49 CFR which contains its own tank construction requirements.

Materials that meet the criteria of Division 6.1 on the basis of their toxicity by inhalation are referred to as "poison by inhalation" (PIH) materials which are subject to special packaging, marking, labeling, and transport document requirements. It should be noted that a number of substances have been found to meet the criteria of PIH materials, even though this is not reflected by their UN classification.

Gas cylinders used in transport must meet construction requirements in 49 CFR.

Explosives, including materials that exhibit explosive properties, require special authorization by RSPA.

Emergency response information must accompany hazardous materials shipments, and the transport document must include a telephone number where additional information on the material may be obtained at any time while the material is in transport.

Training requirements apply to shippers and carriers that bring hazardous materials into the United States

Additional restrictions pertaining to the transport of radioactive materials are included.

The requirements also include special provisions relating to air transport.

Under 49 CFR 171.12 (c), fewer special provisions apply when hazardous materials transported in accordance with the IMDG-Code are transported within a single United States port area.

5.2.3. Japan

Japanese regulations for transport of dangerous goods by rail and road exhibit some differences from those of European countries and the United States. International carriage of dangerous goods by sea and/or air is subject to the domestic regulations based on the IMDG-Code and ICAO Technical Instructions, but for inland transport by rail and/or road, the current regulations are not based on United Nations or other international recommendations. Dangerous goods can be transported from foreign countries to Japan by ship or aircraft under common classification, packaging, labeling, marking, etc., in compliance with IMDG-Code or ICAO Technical Instructions, but for inland transport by rail and/or road, carriage is regulated by Japanese requirements. In Japan, dangerous goods are regulated en bloc for manufacturing, storage, transportation, consumption, etc., except for regulation of carriage by ship and aircraft.

Japanese regulations for transport of dangerous goods are summarized as follows.

Sea transport is regulated by the following laws:

1) Ships Safety Law. Transport requirements for dangerous goods by ship are provided in the Regulations for Carriage and Storage of Dangerous Goods by Ship as an order of the Ships Safety Law, in which almost all of the IMDG-Code has been adopted.
2) Port Regulation Law. This provides for berthing and cargo handling of a ship carrying dangerous goods in port, but not packaging, labeling, marking, etc., which must be in accordance with the Ships Safety Law.

Air transport is regulated by the Civil Aeronautics Law. This prescribes transport requirements regarding classification, packaging, labeling, marking, etc., and complies the requirements of ICAO Technical Instructions.

Inland transport of dangerous goods is implemented in Japan under comprehensive regulations regarding manufacturing, storage, transport, consumption, etc. Classification, packaging, etc. for transport are not based on international recommendations.

1) Fire Service Law. This provides requirements for storage, road tank vehicles, means of road transport, emergency procedures, etc. It covers Classes 3, 4 and 5 of the UN Recommendations, with some differences in classification criteria.
2) Railway Operation Law. Requirements for carriage of dangerous goods by rail are regulated by this law, but classification, packaging, labeling, marking, etc. are subject to other inland transport regulations, such as the High-Pressure Gas Control Law and the Explosives Control Law. It covers all classes of the UN Recommendations, with some differences in classification criteria.

3) High-Pressure Gas Control Law. Storage, packaging, transport, etc. of gases on land are regulated by this law. Classification criteria are different from the UN Recommendations.
4) Explosives Control Law. Manufacturing, storage, transport, sale, consumption, etc. of explosives are regulated by this law. The Classes and Divisions of the UN Recommendations are not adopted.
5) Poisonous and Deleterious Substances Law. Import, manufacturing, sale, handling, transport, etc. of poisonous and irritant substances are regulated by this law. It covers Classes 6.1 and 8 of the UN Recommendations, with some differences in classification criteria.
6) Law for the Regulation of Nuclear Source Materials, Nuclear Fuel Materials, and Reactors. This provides land transport requirements, e.g., packages, test procedures, radiation protection, for nuclear materials. It adopts IAEA Regulations (SS 6).
7) Law for the Prevention of Damage from Radioactive Isotopes. This law provides land transport requirements, e.g., packages, test procedures, radiation protection, for radioactive materials other than nuclear materials. It adopts IAEA Regulations (SS 6).

6. Containment Technology

6.1. Transport of Piece Goods

Shipment of dangerous goods in packed form, i.e., in packagings or intermediate bulk containers (IBC), is still the most common means of carriage from one site to another by all modes of transport.

6.1.1. UN Packagings, "Packagings by Description", Intermediate Bulk Containers

In its *Recommendations on the Transport of Dangerous Goods* [41], the UN Committee of Experts on the Transport of Dangerous Goods has issued a set of provisions to provide as much safety for the transport of dangerous goods as possible with regard to the needs of all parties concerned, e.g., administrators, commercial companies, or the public.

The recommendations on the packing of dangerous goods form the basis for existing international [42–45] and national regulations. Account is also taken of a prevailing trend to replace the detailed specification/description by tests designed to ensure that the packaging or IBC can withstand normal conditions of transport, and to ensure a desirable level of safety.

6.1.1.1. UN Packagings

Types of Packagings. For the so- called UN Packagings, the types of packaging are defined as follows:

Bags: flexible packagings made of paper, plastic film, textiles, woven material, or other suitable materials.

Boxes: packagings with complete rectangular or polygonal faces, made of metal, wood, plywood, reconstituted wood, fiberboards, plastics, or other suitable material.

Drums: flat-ended or convex-ended cylindrical packagings made of metal, fiberboard, plastics, plywood, or other suitable material. Wooden barrels of jerricans are not covered by this definition.

Jerricans: metal or plastics packagings of rectangular or polygonal cross-section.

Wooden barrels: packagings made of natural wood, of round cross-section, having convex walls, consisting of staves and heads, and fitted with hoops.

There are two more complex forms of dangerous goods packagings:

Combination packagings: consist of one or more inner packagings secured in an outer packaging in such a way that they cannot break, be punctured, or leak their contents into outer packagings (usually boxes).

Composite packagings: consist of an outer packaging and an inner receptacle, constructed so as to form an integral packaging. Once assembled, it remains thereafter an inseparable unit; it is filled, stored, transported, and emptied as such.

General packing requirements applicable to the packing of substances of all classes other than Classes 2 and 7 define the design and behavior of packagings. It is required that these

should be constructed and closed so as to prevent any leakage which might occur under normal conditions of transport, by vibration, or by changes in temperature, humidity, or pressure. Parts of packagings which are in direct contact with dangerous substances should not be affected by chemical or other action of those substances, or should be provided with a suitable inner coating or treatment, e.g., a liner.

The packagings should be manufactured and tested under a quality assurance program which satisfies the competent authority that each manufactured packaging meets the requirements of the design type.

Testing and Approval. Requirements in the regulations for package strength are expressed as performance standards or tests. The regulations prescribe what must be achieved, rather than how itis done. Therefore, the most important item is that each packaging, except inner packagings of combination packagings, should conform to design types successfully tested, as set out in the regulations and in accordance with procedures established by the competent authority. The testings consist of drop tests (for all design types) and stackings tests (for all design types except bags and nonstackable composite packagings). Packagings intended to carry liquids, i.e., drums, jerricans, additionally have to pass hydraulic pressure tests and leakproofness tests; if they are made of plastics they also have to prove the compatibility of the plastics materials with the contents, i.e., prestorage for six months with the liquid(s) intended or with so-called standard liquids: wetting solution, acetic acid, *n*-butyl acetate/*n*-butyl acetate-saturated wetting solution, mixtures of hydrocarbons (white spirit, nitric acid, or even water). The latter standard liquids only apply to defined high molecular mass polyethlene packagings. These are the so-called compatibility tests.

Tests must be carried out on packagings and packages prepared as for despatch, including inner packagings of combination packagings. The packagings shall be filled to not less than 95 % of their capacity for solids or 98 % for liquids. A given number of test samples have to pass the tests in such way that the weakest part of the packaging is tested. The severity of the test conditions depends on the packing group(s) (PG) for which the packaging is intended.

There are drop tests from three different heights: 1.8 m for PG I, 1.2 m for PG II, or 0.8 m for PG III. Where the relative density of a liquid to be carried is greater than 1.2 g/cm^3, the drop height (in meters) is calculated on the basis of the relative density by multiplying it by 1.5 for PG I, by 1.0 for PG II, and by 0.67 for PG III. The drop tests are carried out on a target with a rigid, nonresilient, flat, and horizontal surface, having mass 50 times that of the test specimen (see ISO 2248).

There are two different air pressures for the leakproofness test, i.e., not less than 30 kPa for PG I or not less than 20 kPa for PG II and III.

The hydraulic (or internal) pressure test to be applied depends on the vapor pressure of the filling substance, normally at 55 °C, but must not be less than 100 kPa.

The stacking test must prove that the test samples can withstand an additional mass equivalent to a stacking height of at least 3 m.

There are additional tests such as the permeability test for plastic drums and jerricans when used for flammable liquids with flash point < 55 °C, or a supplementary test for wooden barrels.

The competent authority may also establish procedures for the approval of packagings, now common practice in countries which have adopted the UN Recommendations or international regulations derived therefrom into national law.

Coding System and Marking. In order to identify the packagings with their design and tested properties, a system of coding and marking has been developed. The code consists of an arabic numeral indicating the kind of packaging, e.g., 1 for a drum, 3 for a jerrican, 4 for a box, or 5 for a bag, followed by one or more capital letters indicating the nature of the material, e.g., A for steel, G for fiberboard, H for plastics, etc., followed where necessary by an arabic numeral indicating the category of packaging, e.g., 1 when the packaging is designed with a nonremovable head or a closure with diameter ≤ 70 mm, 2 for a removable head or a closure with diameter > 70 mm. There are additional coding provisions for composite packagings and packagings manufactured to different specifications.

The complete marking of a dangerous goods packaging, having met the UN Recommendations and been approved by a competent authority, normally consists of the UN symbol followed by the packing code; a code in two parts, i.e., the letter X, Y, or Z designating the packing groups I, II, or III for which the design type has been approved and the relative density (liquids) or the maximum gross mass in kilograms; either a letter S (solids or inner packagings) or, where a hydraulic pressure test has been passed, the test pressure in kPa; the year of manufacture (last two digits); the mark of the state in which the approval was issued; and an identification mark specified by the competent authority.

Typical markings are for example:

UN 1A1/X/250/94/D/BAM 1234-00, where 1A1 means a steel drum with openings of diameter < 70 mm, submitted to drop tests from a height of 1.8 m, and tested at an internal hydraulic pressure of 250 kPa. The certificate of approval has been issued for PG I by the *Bundesanstalt für Materialforschung und -prüfung* (BAM) in Berlin, being the competent authority in Germany, the registration number is 1234, and the drum was manufactured in 1994 by a company with registration letters 00. This steel drum can be used for liquids of packing groups PG I, II, and III.

Or another example:

UN 4G/Y 20/S/94/D/BAM 9876-QQ, where 4G means a fiberboard box, submitted to drop tests from 1.2 m. The box can be used for solids of PG II and III or inner packaging(s) with substances of PG II and III. Here too the certificate of approval has been issued by the BAM in Germany; the registration number is 9876, and the box was manufactured in 1994 by the manufacturer with the registration letters QQ.

6.1.1.2. Packagings by Description

Though the system of tested and approved design types of packagings has been established for dangerous goods of Classes 1, 3, 4.1, 4.2, 4.3, 5.1, 5.2, 6.1, 6.2, 8, and 9, there are still so-called described packagings, especially for Class 2, and in some cases 7. There are provisions for materials properties, e.g., aluminum alloy receptacles for certain gases of Class 2, or steel receptacles. The same applies for packagings intended for the shipment of low-specific-activity radioactive material (LSA-I) of Class 7, where provisions for general conditions of packagings also apply with no particular requirements for testing.

Class 2 is under revision, and it is planned to establish provisions for the testing of the appropriate packagings.

6.1.1.3. Intermediate Bulk Containers (IBC)

An intermediate bulk container (IBC) is a rigid or flexible portable packaging, other than specified in Section 6.1.1.1, that has capacity ≤ 3000 L (≤ 250 L for sea transport) is designed for mechanical handling, and is resistant to the stresses produced in handling and transport as determined by specified tests. Typically, IBCs are intended for multimodal transport of PG II and III substances.

Types of IBC. *Metal IBCs* consist of a metal body together with appropriate service and structural equipment.

Flexible IBCs consist of a body constituted of film, woven fabric, or any other flexible material, or combination thereof, together with any appropriate service equipment and handling devices.

Rigid plastics IBCs consist of a rigid plastics body, which may have structural equipment together with appropriate service devices.

Composite IBCs with plastics inner receptacles consist of structural equipment in the form of a rigid outer casing enclosing a plastics inner receptacle, together with any service or other structural equipment. They are so constructed that the inner receptacle and outer casing once assembled form, and are used as such, an integrated single unit to be filled, stored, transported, or emptied as such.

Fiberboard IBCs consist of a fiberboard body with or without separate top and bottom caps, if necessary an inner liner (but no inner packagings), and appropriate service and structural equipment.

Wooden IBCs consist of a rigid or collapsible wooden body, together with an inner liner (but no inner packagings) and appropriate service and structural equipment.

The IBCs must be so constructed and closed that none of the contents can escape under normal conditions of transport. All service equipment must be so positioned or protected as to minimize the risk of leakage owing to possible damage during handling and transport. The IBCs must be designed, manufactured, and tested under a quality assurance program which satisfies the competent authority, in order to ensure that each manufactured IBC meets the given requirements.

Testing and Approval. The design type of each IBC must be tested and approved by the competent authority. For each design type, a single IBC must pass the required tests before such an IBC is used. An IBC design type is defined by the design, size, material, and wall thickness, manner of construction, and means of filling and discharging; it may include various surface treatments.

Test shall be carried out on IBCs prepared for despatch, i.e., filled either with the contents intended to be carried or with other substances having at least equivalent physical properties, e.g., mass, grain size, relative density. For the latter, the same calculation procedure used for packagings can be applied.

The main test provisions are:

– A bottom lift test for each design type to be handled in this way, except for flexible IBCs
– A top lift test for metal, flexible, rigid plastics or composite IBCs
– A tear test for flexible IBCs
– A stacking test for all design types
– A leakproofness test for IBCs intended to carry liquids
– An internal hydraulic pressure test for IBCs intended to carry liquids
– A drop test for all design types; another IBC of the same design may be used
– A topple test for flexible IBCs only
– A righting test when a flexible IBC is designed to be lifted from the top or from the side

Coding System and Marking. The code system for IBCs consists of two arabic numerals indicating the type of IBC, a capital letter indicating the nature of the material and, where necessary, an arabic numeral indicating the category of IBC within the type. For composite IBCs, two capital letters are used; the first indicates the material of the inner receptacle, and the second that of the outer packaging.

Rigid IBCs for solids are coded 11 if loaded and/or unloaded by gravity, 21 if loaded and/or unloaded under pressure > 10 kPa, and 31 if intended to carry liquids. Flexible IBCs are coded 13.

The nature of the material is indicated by A for steel (all types and surface treatments), B for aluminum, C for natural wood, D for plywood, F for reconstituted wood, G for fiberboard, H for plastics, L for textiles, M for paper (multiwall), and N for metals other than steel or aluminum; i.e., the letters are the same as for the materials of packagings.

The IBC code is followed in the marking by a letter indicating the packing group(s), i.e., Y for PGs II and III, Z for PG III. The use of IBCs for PG I substances is still under discussion, and up to now scheduled only for certain solids.

Deviating from the marking system of packagings, there is a so-called primary marking consisting of: the UN symbol; the design type code; the letter for the packing group(s); the month and year (last two digits) of manufacture; the mark of the state in which the approval was issued; the name or symbol of the manufacturer, or any other identification as specified by the competent authority; the stacking test load in kilograms; and the maximum permissible gross mass or, for flexible IBCs, maximum permissible load in kilograms.

Additional marking follows the primary one, namely the tare mass (kg) for all IBCs other than flexible IBCs; for metal IBCs, rigid plastics IBCs, and composite IBCs the capacity (L at 20 °C); the date of the last leakproofness test (month and year), if applicable; date of last inspection (month and year); and the maximum filling/discharge pressure (kPa), if applicable. For metal IBCs only, the marking is completed by indicating the body material and its minimum wall thickness (mm) and the serial number of the manufacturer. For rigid plastics IBCs and composite IBCs, the test pressure (gauge) in (kPa), if applicable, concludes the marking.

A typical marking of a metal IBC could be: UN 11A/Y/0394/NL/Van Hoog 001/5500/1500, where 11A means a steel IBC for solids discharged, e.g., by gravity, for PG II and III;

manufactured in March 1994; approved by The Netherlands; manufactured by van Hoog in conformity with a design type to which the competent authority has allocated the serial number 001; load used for the stacking test 5500 kg; maximum permissable gross mass 1500 kg.

Operational Requirements. Before being filled and handed over for transport, every IBC must be inspected to ensure that it is free from corrosion, contamination, or other damage, and with regard to proper functioning of any service equipment.

When filled with liquids, sufficient ullage shall be left to ensure that, at the mean bulk temperature of 50 °C, the IBC is not filled to more than 98 % of its water capacity.

During carriage, no dangerous residue should adhere to the outside of an IBC. Also, IBCs must be securely fastened or contained within the transport unit so as to prevent lateral or longitudinal movement or impact, and to provide adequate external support.

After discharging, an empty IBC must be treated as for a filled IBC, unless it has been purged of the residue of the dangerous substance.

Where IBCs are used for the transport of liquids with a flash point ≤ 60.5 °C (closed cup, see also page **??**) or powders liable to dust explosion, measures must be taken to prevent a dangerous electrostatic discharge.

6.1.2. Packagings for Radioactive Material

Required packaging for radioactive material (RAM) is based on the assurance that the level of safety built into such a packaging meets the potential hazards of the contents being shipped. Because of the specific dangers arising from RAM, there are special regulations to ensure their safe transport [46, 47].

There are four primary types of package, relating to the activity and physical form of their radioactive contents: excepted packagings, industrial packagings, type A packagings, and type B packagings.

An *excepted package* contains quantities of RAM sufficiently small (e.g., smoke detectors) to allow their exception from most design and use requirements. Such packages must, however, meet certain requirements which ensure that their contents can be identified when opened, and that they can be safely handled and transported. These include design requirements to assure safe handling and stowage of the package, and to exclude adverse effects of shock, vibration, collection and/or retention of water, and chemical or radiolytic degradation of the packaging materials.

Because of the extremely low hazard posed by the contents of excepted packages, they may be transported with limited administrative controls, and without externally visible warning labels. Local postal regulations may permit certain packages of this type to be shipped by mail.

Industrial packages are used to transport materials known as either low specific activity (LSA) or surface- contaminated objects (SCO). Materials of low specific activity, having little activity per unit mass, and certain nonradioactive objects, having low levels of surface contamination, are safe for two reasons: either the contained activity is very low, or the material is in a form which is not easily dispersed and which presents only a low internal radiation hazard.

Materials of low specific activity, such as radioactive ores, can sometimes be transported unpackaged. Otherwise, these materials are transported in industrial packages.

In addition to meeting the requirements for excepted packages, industrial packages must meet requirements relating to normal conditions of transport which include minor mishaps. Industrial package integrity is graded in relation to the hazard posed by its contents. There are three types:

Industrial packages type 1 (IP-1) must meet certain temperature and pressure requirements beyond those imposed on excepted packages
Industrial packages type 2 (IP-2) also have to pass free drop and stacking tests
Industrial packages type 3 (IP-3) must in addition meet water spray and penetration test requirements

Type A packages are intended to provide a safe, economical means to transport relatively small quantities of radioactive material: they are expected to retain their integrity under "normal" abuse, i.e., quite likely to occur during transport:

Falling from vehicles or being dropped from similar heights
Being struck by a sharp object which may penetrate the surface
Being exposed to rain
Having other cargo stacked on them

These packages must be designed to satisfy all the requirements imposed on an IP-3 package, and must also meet more stringent test requirements if the radioactive content is liquid or gaseous. They must also satisfy stringent dimensional, ambient environment, internal pressure, and containment specifications which are not imposed on industrial packages.

It is assumed that Type A packages may be damaged in a severe accident, and that a fraction of their contents may be released. The regulations therefore prescribe limits on the maximum amounts of radionuclides that can be transported in such packages. These limits ensure that in the event of a release the risks from external radiation or contamination are low.

In addition to normal environmental conditions, such as high and low pressure, and to reduced atmospheric pressure as sustained by the excepted and industrial packages, Type A packages must be able to retain their contents and shielding integrity if subjected to:

1) The free drop test, where the test specimen is dropped onto a nonresillient hard target so as to cause maximum damage to the safety features to be tested. The normal drop height is 1.2 m. Heavier packages, of more than 1.5 t are dropped from a lower height ($\geq$0.3 m). Where a package is intended to carry liquids or gaseous contents the drop height is 9 m.
2) The compression (stacking) test, where the package is subjected for a period of 24 h to a load equal to or greater than five times the mass of the actual package.
3) The penetration test, where the packaging is placed on a rigid, flat, horizontal surface, and a bar of mass 6 kg and 3.2 cm diameter with a hemispherical end is dropped from a height of 1.0 m (1.7 m if the package is intended to carry a liquid or gas), with its longitudinal axis vertical, so that it falls onto the center of the weakest point of the package.

Type B packages are used to carry larger amounts of radioactive material. They must be able to withstand the effects of servere accidents; tests for resistance to immersion, representing hypothetical accident conditions, are required. Additionally, each design must be approved by the competent authority of the country in which the package was designed; and under some conditions, by the competent authority of each country through or into which it is shipped.

Type B packages are used for carrying radioisotopes for industrial radiography, irradiated nuclear fuel, nuclear wastes, and similar highly radioactive material. Type B packages must be capable of withstanding both Type A and Type B tests.

Packages Designed for Fissile Materials. This type of package is required if the contents are capable of sustaining a nuclear chain reaction. Special assessments and controls are required for such packages. And each design must be approved by the competent authority of each country from, through, or into which it is shipped.

Type A and B packages and packages for fissile materials also have to meet specific requirements. These are:

Mechanical tests, where any given packaging must pass two tests. In most cases, an impact (or drop) and a penetration (or puncture) test are required. These consist of dropping a test specimen onto two different targets so to cause maximum damage. In one drop test, the packaging is dropped from a height of 9 m onto a unyielding surface, in the other it falls onto a mild steel bar, 15 cm in diameter, from a height of 1 m. The bar is rigidly mounted, perpendicular to the target surface, and must project at least 20 cm above the base. An alternative to the 9 m drop test for some lightweight Type B packages is the so- called *crush-test*. This consists of placing the packaging on the unyielding target in such a way as to experience the maximum possible damage when a 500 kg steel mass is dropped onto it from a height of 9 m.

Thermal test, where the packaging is fully engulfed in a thermal environment of at least 800 °C for 30 min. Any combustion of the packaging's components must be allowed to continue self-extinction.

Water immersion test, where most packagings are immersed in water at a pressure equivalent to a depth of at least 15 m for not less than

8 h. A water immersion test applicable to some packagings for irradiated nuclear fuel requires immersion in water at a pressure equivalent to a depth of at least 200 m for not less than 1 h resulting in no leakage.

Means for identifying shipments of radioactive material are: labels (with the trefoil symbol); markings assigned by the competent authority – both labels and markings must be visible on the packaging; and/or placards (with the trefoil symbol) on vehicles, rail cars, freight containers, and portable tanks.

As outlined earlier, safety in transport depends primarily on the integrity of the packaging. In particular, packages designed for dangerous goods and especially those for the transport of materials with high potential hazards are designed and manufactured to the highest engineering standards to meet the requirements of the transport regulations. The regulations for the transport of radioactive materials were the first to contain specific provisions on quality assurance (QA) for all transport operations; QA is defined as any systematic evaluation and documentation of performance judged against regulatory requirements. Where approval of the competent authority is required for a design or shipment, such must be contingent on the adequacy of a QA program.

6.1.3. Consignments, Means of Loading, and Loading Security

The shipment of dangerous goods from one site to another on public routes involves a number of measures. These are covered by the so- called consignment procedures. The whole cycle from the manufacturing of the substance or product to its final use is a complex interaction of all parties and measures involved.

The manufacturer has to inform the consignor of any dangerous properties. The packer has to choose the admissible packaging or IBC, to take care of any prohibition of mixed loading, and to be responsible for the correct marking and labeling of the packages or IBCs. The consignor has to ensure proper documentation for the shipment, including the transport document containing at least: a description of the goods, including the substance identification number (where available); the class; necessary initials (if any); the number and a description of the packages or IBCs; the gross mass; the names and addresses of the consignor and consignee(s); and/or declaration required by the terms of any special arrangement. The carrier has to take care that all relevant and necessary information about the load and the transport documents be handed to the driver, that no damaged packages have been loaded, that the necessary testing certificates for tanks or tank containers are available, that filling limits have been observed, and all necessary labeling of the vehicle or container has been applied. There are additional requirements for the driver and assistant (if any) as well as for the vehicle itself [44].

The various components of a dangerous goods load must be properly stowed on the vehicle and adequately secured to prevent them from being displaced in any way in relation to each other and to the walls of the vehicle. Minor displacements may be permitted, provided they are of a stabilizing nature, and do not lead to constant frequent motions of the load in the cargo space. If the load comprises goods from different categories, the packages of dangerous goods have to be separated from the others. The load has to be uniformly distributed over the loading space, and/or sufficiently secured against slipping backwards, sideways, or falling out. Packages must be stowed so they are protected from any penetration or impact, and from being squeezed, punctured, or exposed to a pressure which might break the package. This can be achieved by clamping beams, brackets, pads, or dunnage baulkings. Cargo spaces and packages or IBCs must be clear of oil, ice, or other covering which may reduce friction. Most accidents in transportation are due to improper loading security measures, and carriers or shippers of dangerous goods must ensure appropriate loading security.

6.2. Bulk Transport

A bulk shipment is the transport of a loose, unpacked material (gas, liquid, or solid) in a means of transportation (Fig. 5).

	Bulk transport	
	Liquids, gases	Solids
Road and rail transport	Tank containers Tank trucks Rail tank wagons	Containers, tank containers, bulk containers Tank trucks, silo trucks Sheeted or open, covered vehicles with box-type construction
Marine transport	Ships	
Air transport	Not permitted	

Figure 5. Overview of packagings for bulk transport

Different definitions of the "packed state" of a material apply for the individual carriers.

For shipment by rail and road, dangerous goods are considered packed when they are present in tested and permitted packagings according to Appendix A.5 of ADR [48] or Appendix V RID [49] (max. volume 450 L) or in tested and permitted intermediate bulk containers according to Appendix A.6 ADR or A.VI RID (max. volume 3000 L). For ocean and inland-waterway transport, road and rail vehicles as well as containers already represent a so-called bulk packaging [50].

However, because of the large quantities which are shipped in one packaging, shipment in bulk represents a higher potential of release. Therefore, only less dangerous substances are permitted for this mode of carriage or the packaging for this mode of carriage or the packaging must be designed to be adequately safe (e.g., double wall). The logistic chain is often greatly simplified by bulk shipment, the number of shipments required is greatly reduced, and savings by orders of magnitude are made in packing material.

6.2.1. Bulk Transport of Liquids and Gases

6.2.1.1. Tank Containers [42,51–56]

In the transport of gaseous and liquid goods (as well as granular materials and powders, see also Section 6.2.2), the tank container is one of the most widely used means of transport equipment.

Tank containers are equally suitable for all transport routes (water, road, rail) and therefore, as a multimodal means of transport, offer a variety of possible uses.

These possibilities range from transport via intermediate storage up to long-term storage or stockpiling of goods. With regard to the design and manufacture of the tank, and its testing and operation, regulations (IMDG-Code, based on the UN recommendations) and standards (ISO) valid and accepted worldwide must be observed.

It must be demonstrated by calculation that the tank container withstands the planned loads, i.e., internal and external overpressure and the load which results from the inertia of the tank's contents during movement in transport. The tank, including its attachment fittings, must be able to absorb the following forces at the highest permissible weight of its contents:

1) Twice the total weight in the direction of travel
2) The total weight horizontally perpendicular to the direction of travel (if the direction of travel is not clearly defined, twice the total weight applies in each direction)
3) The total weight vertically upwards
4) Twice the total weight vertically downwards

With these forces acting, there must also be a safety factor of at least 1.5 relative to the elastic limit.

The tank material must be resistant to the cargo or be protected by a resistant lining or coating. Items of equipment on the tank container must be so mounted that during transport or handling they are secure against tearing off or damage. They must guarantee the same safety as the tank, and remain leak-free if the tank container turns over.

Tanks with discharge underneath must be provided with two independent closures in series, the first of the two closures being internal.

Each tank container licensed under the IMDG-Code must be fitted with a pressure-compensating device. This can consist of a melting fuse, a bursting disk, or a pressure-relief valve and must be approved by the responsible authority.

The total amount blown off by the presssure-compensating device from a tank completely surrounded by fire must be sufficient to limit the pressure in the tank to a value of 20 % above the response pressure of the pressure-compensating device.

Each tank container is subject to a type license by the national licensing authority concerned.

Tank containers built according to this license, including their items of equipment, have to be tested before being brought into service and subsequently at regular intervals by experts recognized by the authorities.

In the operation of tank containers the maximum degree of filling must be observed. In tanks of capacity >7500 L, to avoid forces arising from the surging of liquids, a minimum degree of filling of 80 % must be observed, or surgeobstructing arrangements provided.

As a result of the regulations valid and applied worldwide it is guaranteed that tank containers satisfy a uniformly high standard of safety engineering.

6.2.1.2. Tank Trucks and Railroad Tank Cars [51,52,57–64]

In addition to the transport of dangerous materials in tank containers, transport in tank trucks and railroad tank cars is of great importance.

A tank truck is a vehicle with one or more tanks fastened to it for the transport of liquids and gases, as well as powders and granular solids (see also Section 6.2.2).

For *tank trucks,* aside from the constructional and equipment requirements of the actual tank, which are comparable with those of tank containers, the following requirements with regard to the electrical and nonelectrical equipment of the vehicle must be observed.

The rear of the vehicle must be protected against collision by a bumper over the whole width of the tank.

In vehicles that transport liquids with a flash point of <61 °C or flammable gases, the vehicle engine, the exhaust pipes, and the loading pump (if present) must be constructed such that danger to the load resulting from heating or ignition is avoided.

The vehicles' fuel tank must be so arranged that it is protected as well as possible in a collision. If fuel nevertheless escapes, it should be able to run off directly to the ground. Positioning of the fuel tank directly above the exhaust arrangement is not permitted.

In many countries the quality of the vehicles' braking system is subject to testing at regular intervals.

Tank trucks carrying dangerous materials must be equipped with at least one portable fire extinguisher, mainly intended for extinguishing burning tires.

Special requirements must be met by the electrical equipment of a vehicle if liquids with a flash point of <61 °C, combustible gases, or certain explosives are transported:

1) Sufficient dimensions of the cables to avoid overheating
2) Adequate insulation
3) Protection of the leads from impacts, stones, and the heat from the exhaust arrangement
4) Fitting of a battery isolation switch in the driver's cabin or outside on the vehicle, which breaks all circuits in the event of danger

The use of safety valves to avoid unacceptably high pressure in the tank is not uniformly prescribed. In land traffic, it is mainly tightly sealed tanks that are transported.

Arguments against fitting with safety valves are, in particular:

1) Possible operation of the valves (e.g., in tunnels or when driving through built-up areas), whereby the operation is possibly not noticed
2) Possible gumming-up of valves with product and, therefore, failure to function
3) Experience with valves "flaring off" has shown that after a short time the tank and valve material is annealed and loses strength, which can then lead to a tank explosion

Arguments for using safety valves are:

1) In the case of overfilling, overstressing of the tank by hydraulic pressure is avoided
2) The noise of the valve blowing off serves as an indication of danger

As is prescribed in many countries, the drivers of tank trucks should possess a certificate demonstrating that they have taken part in training and have passed an examination on the special requirements to be met in the transport of dangerous materials.

Railroad tank cars consist of an assembly of one or more tanks and the underframe. The basic requirements for the tanks with regard to construction, equipment, and testing are comparable with those for tank containers and tank trucks. Requirements specific to the railroad are set for the underframe, consisting of running carriage, suspension, drawgear, and buffer gear, and for the brakes.

Within the scope of application of ADR and RID, as described in Section 6.2.1.1, both tank trucks and railroad tank cars are subject to type approval by the responsible authorities and regular testing by officially recognized experts.

6.2.1.3. Marine Tankers [65–73]

Whereas the transport of liquids in tank vehicles and tank containers by land is considered to be bulk transport, in shipping, such transport in units regarded as "bulk packaging" is carried out in accordance with the rules for packed dangerous goods. The term bulk cargo is used if unpacked material is taken into the ship's tanks.

The requirements for such ships for the field of ocean shipping are contained in the SOLAS (*International Convention for the Safety of Lifes at Sea*) Conventions and MARPOL (*International Convention for the Prevention of Pollution from Ships*) as well as in the IBC (*International Bulk Chemical Code*) and IGC (*International Gas Carrier Code*) Codes, and the requirements for inland navigation in the ADN and/or ADNR Regulations. Supplementary dimensioning and construction regulations are contained in the appropriate classification and construction rules of internationally recognized classification corporations (e.g., Germanischer Lloyd).

In view of the increasing oil pollution of the oceans and environmental protection in general, measures for raising the standard of safety both in inland-waterway and ocean shipping have been introduced stepwise in the above-mentioned regulations, or have come into force in 1995 for inland shipping and for existing ships in ocean shipping.

Inland Shipping. Inland navigation dispenses with its own list of substances and adopts, with a few additions, that of the land traffic regulations by direct reference in Marginal no. 6002 1a to Appendix A of ADR in its current version. Problems in the transport of packed dangerous goods on transfer from land transport to inland shipping are therefore excluded.

Bulk transport in tankers is permitted only for products listed in Appendix B 2. This list at present contains ca. 270 entries for directly named substances and N.O.S. products of Classes 3 and 8 to which a UN number has been allocated. The list is to be regarded as open, i.e., it can be extended after examination of a request to transport. The time until acceptance is bridged by exemptions regulations limited to one year, according to a precisely defined procedure.

As a result of the requirements included in the substance list for the products and further substance-related regulations in Part II of Appendix B 2 of ADNR, the tanker regulations of the new ADNR are now related to substance rather than type of ship.

In spite of substance-related construction regulations, there are still three types of ship, which however can now be regarded only as a rough classification. The allocation of any product to one of the three types of ship

Type G tanker (gas tanker)
Type C tanker (chemicals tanker)
Type N tanker (normal tanker) is given in the substance list.

The *Type G Ship* is a tanker intended for the transport of gases. Transport is normally carried out in the liquefied state, either under pressure at ambient temperature or at cryogenic temperatures and atmospheric pressure. Partial cooling and transport in pressure tanks is also possible.

For the transport of liquefied gases under pressure, the hull must be constructed in the cargo area as follows:

1) As a double-hull ship with wing walls and double bottom minimum wing-wall width 0.8 m minimum double-bottom height 0.5 m
2) As a single-hull ship with reinforced side-wall structures minimum distance cargo tank – side wall 0.8 m minimum distance cargo tank – bottom 0.6 m
3) Other designs, provided a collision energy of at least 22×10^6 Nm is attained.

The maximum permissible tank capacity depends on the size of the ship (LBH value), but

must in no case exceed 380 m^3 per tank. A minimum number of tanks is no longer prescribed, but proof must be provided of sufficient damage stability when two adjacent compartments spring a leak under precisely defined damage conditions. When the main engine room springs a leak, only the single-compartment status has to be proved.

The *Type C Ship* is a tanker designed for the transport of especially dangerous liquids, such as poisons of Class 6.1 or combustible liquids of Class 3 with additional dangerous properties such as carcinogenicity and toxicity. This is a flush-deck, double-hull ship with wing walls and double bottom, the cargo tanks in the standard version being formed by the hull.

The use of independent cargo tanks also is permissible if they are installed in the inner holds formed by wing walls and double bottoms.

The minimum width of the wing walls is 1 m, but if certain collision reinforcements are carried out it can be reduced to 0.8 m. The average double-bottom height must be 0.7 m, and this dimension must not be less than 0.6 m at any point.

Apart from the requirement of a maximum permissible tank capacity, a maximum cargo tank length must also be observed. The tank capacity depends on the size of the ship, but must not in any case exceed 380 m^3.

Sufficient damage stability when two adjacent compartments spring a leak has to be demonstrated, whereby certain minimum assumptions of the extent of damage in the event of a leak are made.

Here also, the proof of single-compartment status is sufficient for the main engine room.

There is no need to assume damage to the inner longitudinal bulkhead of the wing walls; likewise the crown of the tank is to be regarded as undamaged, provided the double-bottom height is at least 0.6 m.

Type C double-hull ships with closed tanks must be designed for pressure ratings that rule out a response of the safety valves during the transport of toxic and carcinogenic substances.

A reduction of the safety valve setting can be obtained by additional sprinkling, provided pressure sensors ensure that the sprinkler system comes into operation early enough.

The *Type N Ship* is a conventional tanker for the transport of liquids. These are usually single-hull ships of various pressure ratings for the transport of combustible liquids of Class 3 (comparable with the former tanker Types II to V, but with altered classification criteria).

Acid and alkali tankers for the transport of goods of Class 8 are of this type, even though they are mostly double-hull ships or ships with inserted tanks. With these ships special attention must be paid to material compatibility and it should be noted that acids and alkalis generally have a relatively high density.

Particular distances of tanks from the ship's hull or from the bottom for safety reasons are not required for these ships, nor is proof of damage stability. Sufficient intact stability is, however, prescribed (see Marginal no. 331 214).

In addition to the maximum permissible tank capacity (environmental protection), a maximum cargo tank length must be complied with. The former requirement for a minimum number of tanks has been dispensed with.

There are few restrictions regarding the construction of Type N Ships, so the following alternatives exist, unless they are restricted by the invidual requirements of the substance list:

1) Flush-deck, single hull ship
2) Single-hull ship with trunk
3) Flush-deck, double-hull ship
4) Double-hull ship with trunk
5) Ship with inserted tanks
6) Ship with inserted pressure tanks

The basic safety requirements are the same for all Type N Ships. However, Marginal no. 210 287 (Appendix B 2, Chap. 1) exempts tankers of Type N, open and with and without flame arresters from the observance of a number of requirements.

Thus, the requirements for tankers of pressure rating 0, i.e., those having tanks with an open venting system, are effectively not increased. Only the number of products that can be transported in a tanker with flame arrester has been restricted.

A simplified comparison of the Type N Ships with the former tanker Types I to V is shown in Figure 6.

Ocean shipping has its own list of substances in the IMDG-Code, which in spite of having the same classification, deviates from that of land transport in the ADR, although both

Figure 6. Simplified comparison for Type N Ships with former Type I to V Tankers

originate from the list of substances in the UN recommendations.

The basic regulations for the bulk transport of liquids, as far as dangerous goods are concerned, can be found in Chapter VII of SOLAS and in the MARPOL Convention. These are supplemented by the IBC and the IGC Code.

MARPOL 73/78 is the International Convention of 1973 for the *Prevention of Pollution from Ships* in the version of the protocol of 1978. Appendix 1 of MARPOL 73/78 contains the rules for the prevention of oil pollution by ships and came into force, in part retroactively, on 2 October 1983.

"Oil" here means all petroleum products, including crude oil, fuel, oil sludge, oil residues, and refinery products such as fuel oil and gasoline. "Oil tankers" are defined as ships that transport oil as bulk cargo.

At the 31st MEPC committee meeting in July 1991, the text of the new Rule 13 F for oil tankers was formulated and adopted. It applies to new oil tankers of >600 t load whose construction contract was concluded after 6 July 1993.

Rule 13 F requires for oil tankers of ≥5000 t capacity that the whole cargo tank length is protected as follows by ballast tanks or holds that are neither cargo nor fuel tanks:

1) By wing tanks or spaces over the whole depth to the deck of the ship or from the double bottom to the topmost deck with a width in meters of

$$w = 0.5 + \mathrm{DW}/2000,$$

where DW is the load of the ship in tonnes deadweight (tdw). The minimum value for $w = 1$ m, and the maximum required value is w=2.0 m.

2) By a double bottom with a height in meters of

$$h = B/15,$$

where the minimum value for $h = 1.0$ m and the maximum required value is $h = 2.0$ m (B = breadth of ship).

3) In addition, the total capacity of the ballast tanks must be sufficient for a safe voyage in ballast with the screw fully immersed.

For oil tankers of <5000 t load, equivalent solutions are provided.

As a precursor of MARPOL Rule 13 F, Rule 13 E for crude oil tankers above 20 000 tdw and for product tankers above 30 000 tdw, in effect from 1 June 1979, required a partial double hull by having segregated ballast tanks in a protective arrangement. "Segregated" means that these ballast tanks must be completely separated from the oil cargo and fuel systems; i.e., they can only be used for ballast water. This partial double hull can be formed by a double bottom and/or wing tanks.

The degree of protection J was 0.45 for tankers of 20 000 tdw and 0.3 for tankers of 200 000 tdw. Intermediate values are found by linear interpolation. For tankers of >200 000 tdw J could be reduced to as low as 0.2 according to Rule 23/24, depending on the ratio of the hypothetical to the permissible oil outflow.

In Rule 13 G measures are provided for existing tankers for the prevention of oil pollution in cases of collision and stranding.

Various measures are provided for crude oil tankers of ≥20 000 tdw and product tankers of ≥30 000 tdw for raising the safety standard of existing tanker fleets. These measures can be summarized as follows:

1) Stricter inspections. In addition keeping a complete record of the inspection reports, which is available to the responsible authorities of each of the signatory states.
2) Conversion to a double-hull ship or laying-up after a ship's lifetime of 25 a. For ships that fully satisfy Appendix I of MARPOL 73/78, i.e., those for which the construction contract was concluded after 1 June 1979 (so-called MARPOL tankers), a period of 30 a is laid down.

The requirements of Rule 13 G came into force on 6 July 1995.

It can be gathered from the above that according to Rule 13 F new oil tankers in ocean shipping with a load >5000 t must be built over the whole load range with wing tanks and double bottom, and for those with a load <5000 t equivalent regulations must be observed. However, according to Rule 13 G, for the existing tanker fleet a stricter scope of inspection is required only for crude oil tankers of ≥20 000 tdw and product tankers of ≥30 000 tdw, together with conversion to double-hull ships or laying-up after 25 or 30 years, respectively.

For existing smaller tankers, corresponding precautionary measures have not been agreed upon, so that a definite final date for the existence of small "single-hull tankers" depends on their lifetime, since new ones may not be built.

Apart from the crude oil tankers and product tankers that correspond to the Type N Tankers in inland shipping, ocean shipping has according to Chapter VII of the SOLAS Convention declared the International Bulk Chemical (IBC) Code and the International Gas Carrier (IGC) Code to be binding regulations.

The IBC Code contains material-related regulations for the transport of dangerous liquid chemicals in bulk, allocated to the three types of ship:

1) A *Type 1 Ship* is a chemical tanker intended for the transport of materials that constitute a very great danger with regard to environment and safety and require the highest possible level of safety precautions against the escape of cargo
2) A *Type 2 Ship* is a chemical tanker intended for the transport of materials that constitute a great danger with regard to environment and safety and require considerable safety precautions against the escape of cargo
3) A *Type 3 Ship* is a chemical tanker intended for the transport of materials that constitute a fairly great danger with regard to environment and safety and require a certain measure of safety precautions to improve the buoyancy under damage conditions

Arrangement of the cargo tanks:

Type 1 Ships:	*B*/5 or 11.5 m from the side (the smaller value is required)
	B/15 or 6 m from the bottom (the smaller value is required)
Type 2 Ships:	*B*/15 or 6 m from the bottom (the smaller value is required)
	760 mm from the side
Type 3 Ships:	no requirements (i.e., Type 3 Ships are single-hull ships)

Apart from intact stability, damage stability and buoyancy in the leaking state under specified damage conditions must be demonstrated.

The regulations relevant to substances can be obtained from the substance list, comprising about 800 products, as well as from the special chapters: "Special Requirements," "Additonal Measures for Protection of the Marine Environment," and "Operating Instructions."

The IGC Code governs the sea transport of gases liquefied under high pressure and by cooling. Depending on the potential danger originating from the gas, one of the following specific types of ship is prescribed: Type 1 G Ship, Type 2 G Ship, Type 2 PG Ship, or Type 3 G Ship.

A Type 1 G Ship is a liquefied gas tanker intended for the transport of materials with the highest potential danger, while Type 2 G/2 PG and Type 3 G Ships are provided for the transport of materials with lower potential danger. Accordingly, a Type 1 G ship should be able to survive the severest assumed damage and its cargo tanks have to be arranged at the greatest prescribed distance from the side plating.

If a ship is intended to transport more than one substance of those listed in Section 19 of the IGC Code, the assumptions about damage must correspond to the substance for which the highest demands are made on the type of ship.

The requirements for the arrangement of the individual cargo tanks, on the other hand, refer to the substance actually to be transported in each case.

The Code contains precise specifications with reference to the arrangement of the cargo tanks.

The damage stability and the buoyancy under prescribed damage conditions must be demonstrated, in addition to the intact stability.

6.2.2. Solid Bulk Cargo

Bulk cargo is a loose material (other than liquid or gas) in pourable form [74].

It is characteristic of bulk material that the components or particles are disordered and mutually displaceable, so that the material as a whole has a variable shape and is fluid or pourable. Gravitational force can therefore be exploited for moving bulk material.

Characteristic physical quantities of bulk material are cohesion and adhesion, bulk density, angle of repose, and grain shape and grain size d:

Dust	$d < 0.06$ mm
Fine	$0.5 < d < 10$ mm
Coarse grained	$10 < d < 60$ mm
Medium	$60 < d < 160$ mm
Lump	$d > 16$ mm

These material quantities – together with the hazard properties of the bulk material such as toxicity, gas evolution, corrosivity, infectiousness, flammability, and explosiveness – form the basis for choosing a suitable packaging.

6.2.2.1. Solid Bulk in Road and Rail Transport

Definition. In road and rail transport, the shipment of dangerous material in bulk is defined as "the shipment of a solid material without packaging" [75,76]. This definition is not entirely correct, since by using the term "material" it excludes an important area of bulk cargo shipment: the disposal of uncleaned packages, contaminated objects, and equipment. In general therefore, one should refer to the shipment of solid goods without packaging.

Permitted Goods. The road and rail dangerous goods regulations name three modes of shipment of goods: shipment in bulk, shipment in containers, and shipment in tanks.

This system is illogical and contradicts the definition of shipment in bulk. According to ADR/RID the "bulk" mode of shipment is permitted only for certain materials [76]:

Class	Number	Materials
4.1	4 c)	wastes
	6 c)	all materials and wastes
	11 c)	all materials and wastes
	12 c)	all materials and wastes
	13 c)	all materials and wastes
	14 c)	all materials and wastes
4.2	1 c)	all materials
	2 c)	all materials
	3 c)	all materials
	12 c)	2793 iron metal swarf
	16 c)	1376 iron oxide, used; iron oxide sponge, used
4.3	11 c)	all materials
	12 b)	1405 calcium silicide pieces
	12 c)	all materials
	13 b)	3170 aluminum sweepings
	13 c)	all materials
	14 c)	all materials
	15 c)	all materials
	17 b)	all materials
	20 c)	all materials
5.1	11	all materials and wastes
	12	all materials and wastes
	13	all materials and wastes
	16	all materials and wastes
	18	all materials and wastes
	19	all materials and wastes
	21	all materials and wastes
	22 c)	all materials and wastes
6.1	44 b)	all materials and wastes
	60 c)	all materials and wastes
	63 c)	all materials and wastes
	all in c)	all wastes
6.2	1	all
	2	all
	3	all
	5	all
	9	all
8	1 b	sulfuric-acid-containing lead sludge
	23	all materials and wastes
	all in c)	all wastes
9	4 c)	2211 foamable polymer beads
All		empty (uncleaned) packagings

For all unlisted materials it is forbidden. The selection of materials is not subject to any system but rather is governed by need. Owing to the assumed low safety level of the packings in question, however, the less dangerous materials (c materials) predominate. For some special

areas (e.g., spent accumulators, contaminated soil), there are exceptional national regulations or regulations specific to federal states or special agreements with individual ADR/RID treaty states.

A considerably greater number of bulk materials is permitted according to ADR/RID for shipment in tanks, since relevant constructional, equipment, and testing requirements guarantee a high safety level of the packaging "tank" (see Sections 6.2.1.1 and 6.2.1.2).

Means of Transport and Requirements. For the shipment of bulk material by land, the following means of transport are mainly used (Fig. 7):

1) Open, sheeted, or covered vehicles with box-type construction (dumper trucks)
2) Tank trucks with pressure discharge, or silo vehicles
3) Containers/bulk containers according to ISO 1496/ Part 4 [77]; so-called logistical containers, e.g., put-down containers, according to DIN 30 723 [78] and roller containers according to DIN 30 722 [79]; tank containers

The bodywork of the vehicles is not subject to test requirements. According to the definitions in ADR/RID, a covered vehicle is simply a vehicle whose body can be closed. A sheeted vehicle is one that is provided with a canvas cover to protect the load. The design of the bodywork, like that of containers, remains largely unrestricted in respect of mechanical stability and watertightness.

If materials permitted according to ADR/RID for shipment in bulk are shipped in tank trucks or tank containers, the regulations for construction, equipment and operation of tanks are not applicable [80], i.e., for tank shipment also there are no minimum requirements for stability, watertightness, and equipment.

For the shipment of a number of flammable or spontaneously flammable materials a metallic vehicle construction, and in some cases the use of impermeable or flame-resistant sheeting is also required.

The vehicle bodywork or container for spontaneously flammable materials or materials that evolve flammable gases on contact with water must be capable of airtight closure. For ignitable materials (Class 4.1) and nauseating materials (Class 6.2), sufficient ventilation is prescribed. In the shipment of materials with igniting (oxidizing) effect (Class 5.1), contact with wood or other combustible materials must be prevented.

Figure 7. Bulk container
Top: 12-m silo tank container for the shipment of toxic dust; Bottom: 4-m^3 silo tank for shipment of toxic lead compound

In various fields, particularly in the disposal of industrial wastes, there is a requirement for packages for the collection and shipment of waste, which can guarantee safe disposal of even dangerous wastes, sometimes as heterogeneous mixtures, in large amounts ($>3\ m^3$), and whose construction is adapted to the logistical requirements of an optimum waste-disposal chain (e.g., large openings for filling and emptying).

There have already been a number of special developments whose design is based partly on requirements from the tank field and partly on the regulations for IBCs, as well as additional material requirements (Fig. 8). For these shipment concepts, a special license from the responsible authority is necessary.

Figure 8. Special bulk container for shipment of hazardous waste (Courtesy of HIM)

Starting from the assessment that the current regulations for bulk shipment in land transport do not correspond to the state of the art and do not take sufficient account of the current requirements, a rearrangement of this shipment field is being contemplated that should lead to systematic and clear regulations and objective test requirements.

6.2.2.2. Solid Bulk in Marine Transport

Definition. The regulation for marine and inland-waterway transport define bulk solids as "goods, other than liquids and gases, that can be loaded directly without any intermediate packing into the hold of a ship." Goods are included that are loaded in a barge carrier's lighter on a barge carrier. In addition, the term "bulk package," which refers to packaging (containers, road or rail vehicles) that contain bulk cargo, has been introduced in the field of marine transport [50].

Permitted Materials, Requirements. Solid materials in bulk packages may be shipped in marine transport if, according to the relevant substance page of the IMDG-Code, bulk shipment is permissible. The permissible range of materials corresponds approximately to that in land transport. The materials must be shipped in closed containers or closed road or rail vehicles with superstructures or freight car bodies of metal (dust-tight wooden floors are permissible) or in mobile tanks. The relevant land transport regulations are also to be observed.

For some materials there are also special requirements for the bulk packages. Solid materials that are shipped in bulk in the cargo hold of a ship and from which, because of their chemical or physical properties, a danger originates during transportation are listed in Appendix B of the Code on the Safe Handling of Bulk Cargoes (BC Code).

Some of the materials listed therein represent no substantial danger if they are transported in packagings. However, shipped in bulk, they represent a hazard. These substances include:

1) Aluminum wastes
2) Fly ash
3) Activated carbon, coal, coke
4) Direct-reduced iron, iron phosphide
5) Fluorspar
6) Quick lime
7) Magnesium
8) Pitch
9) Sawdust, wood shavings, wood pellets
10) Silicomanganese
11) Vanadium ore

For materials classified as dangerous goods, the corresponding substance pages of the IMDG Code contain a reference to the BC Code. Before each shipment in bulk of an unlisted material, comprehensive information on the physical and chemical properties of the material can if necessary be obtained by request to the responsible authority.

The prescribed safety measures gathered in the "instructions for the safe handling of bulk cargoes in transportation by ocean ships" are adequate to match the potential hazard of bulk cargoes of dangerous material on ships.

6.3. Cargo Storage

For the storage of goods in packages, logistic considerations, the type of store, and safety requirements all have to be harmonized.

The logistic plan is determined by the type and number of goods, the packing, the storage units (pallet units), the turnover rate, and the type of carrier.

The kinds of storage that must be distinguished are block storage, for large lots of stock units of the same type, and shelf storage, for the storage of single packages and pallet units.

In the design of the store, logistic and safety aspects have to be taken into account:

1) Unroofed open-air storage consists of a paved area, impermeable to liquids, and sufficiently firm. Products can be stored here that are insensitive to temperature and have weather-resistant packing. Individual storage zones are separated by safe distances.
2) In roofed open-air storage the stored goods are shielded from the direct effects of the weather by a self-contained roof structure, but the store has no continuous external walls. The stored goods must be insensitive to temperature. Individual storage zones are separated by safe distances or by walls.
3) In storage buildings, a distinction is made between single-level, multilevel, and racked stores. Products with different safety requirements are accommodated in different store rooms. Storage zones are separated by fire-resistant walls or ceilings. The store is suitably divided into loading zone, handling area, and stocks on hand.

In siting the store facility, sufficient distances must be maintained from residential areas, busy traffic routes, and special protected areas such as drinking water extraction areas. Areas with risk of flood, earthquake, landslide, and avalanche must be avoided. The infrastructure must include good traffic connections, good accessibility for the fire brigade, and a supply of water for fire fighting.

The safety plan for a store must take into account the potential dangers to employees, the neighborhood, and the environment. Control measures serve to avoid a danger arising, to prevent the danger spreading, and to fight the danger. Rules and prohibitions governing storage together of incompatible substances must be observed.

The release of dangerous substances, especially toxic and combustible liquids and gases, is prevented by the choice of corrosion-resistant, stable packing drums, by prohibition of inadmissible overstacking, and by safety devices to prevent falling from shelves.

Escaped product is retained in durable collecting troughs or in the storeroom. The collecting devices must be liquid-tight and product-resistant. With readily volatile liquids and gases, it may be necessary to close openings to the building and switch off the artificial ventilation.

Measures for explosion protection and ventilation are used for the avoidance of fires and explosions, especially with combustible liquids and gases. Ignition sources must be avoided on principle.

The spreading of fire is hindered by constructional arrangements (fireproof walls, ceilings, and load-bearing parts of the building) and by specific store organization (separation of the storage zones by walls and spacings, buffer zones with nonflammable materials). In fairly small storerooms, the spreading of fire can also be hindered by a gas-tight mode of construction and automatic closure of openings (ventilation-controlled fire).

The fire is fought initially by the store personnel, using hand fire extinguishers and wall hydrants. The fire alarm is given by press-button alarm, by telephone, or by automatic fire alarm installations connected to the responsible fire department. The nature, equipment, and speed of the fire brigade must match the danger potential. If the danger potential is considerable, it is necessary to equip the store with automatic extinguishers.

The fire protection plan, including selection of the extinguishing agent, is drawn up with the local fire department. The nature of the fire protection methods also influences the arrangements for retaining contaminated fire-fighting water.

In addition to constructional and technical measures, organizational rules are necessary for the safe and economic operation of a store. In particular:

1) A storage plan and a stock list; both used for rapid information and orientation in the event of danger
2) An internal alarm and accident prevention plan
3) Written instructions for the store personnel on handling dangerous substances, and on rules of conduct in the event of danger

6.4. Bulk Storage

6.4.1. Storage Concept [82–95]

When storage concepts are being developed, the dangerous properties of substances must be taken into account. The optimum amount stored for a store of a given scale follows from production and sales considerations. This can raise an area of conflict between reliability of supply and profitability, on the one hand, and the protection requirements of employees and third parties on the other. Protection of third parties includes neighborhood and environmental protection.

The following forms of stationary tank are customary for the storage of bulk liquids: horizontal and vertical cylindrical tanks, spherical tanks, and flat-bottomed cylindrical tanks in a collecting space. The following types of installation can be considered: above-ground: in the open or in a containment; underground: corrosion-protected; in a collecting space or double-walled or soil- covered with an open end.

The following substance-related risk factors exist: amount stored, pressure, energy potential (product of pressure and capacity), temperature, explosion danger, combustibility, hazard to health, chemical reactivity (e.g., ethylene oxide), corrosion risk (e.g., hydrogen-induced stress corrosion cracking by ammonia in ferritic steels), and danger to water sources. Further intrinsic risk factors arise from the design of the tank system and from processes in which the tank takes place.

The following environment-related risk factors are important: site conditions, fire loads, ignition sources, storage together (layout), foundation (e.g., in mining or earthquake districts), traffic, natural risk factors (e.g., flood danger) and artificial ones. Operational risk factors include human errors in filling, emptying, sampling, cleaning, and maintenance, as well as leaks during operation.

The inclusion of a store in an existing infrastructure reduces risk, e.g., with regard to the reliable supply of energy and water as well as to the immediate engagement of a works fire department.

Changes to existing safety rules must follow the same protective goals. The goals can also be met by other appropriate methods, with consideration of the balance between cost and safety gain.

In this connection, control of disturbances by the third barrier (organizational measures) and the fourth (limitation of consequential damage) must be adequately evaluated when designing the first barrier (tight enclosure) and the second (sufficient safe drainage of any leakage). In works with a well-developed infrastructure, especially in the chemical, petrochemical, and petroleum industries, this third barrier is always readily available.

Principles of a safety plan comprise:

1) Keeping stored amounts small: reducing total amounts stored to the quantity necessary for reliable supply.
2) Lowering the hazard potentials: storage in chemically stabilized or dilute form, mixed with inert carrier material, in solvents, or at low temperature.
3) Distribution: amounts of substance distributed between discrete sections of the store, separated by fire walls.
4) Storing substances separately: this requires that dangerous properties (explosiveness, combustibility, hazard to health) be itemized. For combustible substances it is important to know whether they are readily flammable or even spontaneously flammable; such substances should be stored separately. It is advisable to classify substances into groups according to the transport regulations, extended to include chronic toxicity, carcinogenicity, crop-damaging and genetically modifying properties, and potential danger to water sources. Combustible substances should not be stored together with igniting or spontaneously flammable substances, or with toxic substances, or gases that are compressed, liquefied, or dissolved under pressure.

Avoiding Environmentally Dependent Hazards. It is important to check the site; eliminate fire loads; avoid ignition sources where combustible substances are concerned; separate substances of different danger classes; secure foundations (taking note of soil surveys, earthquake zones); protect against mechanical damage; provide protective distances (e.g., ex-

plosion protection) and safe distances (e.g., from hospitals and schools).

Optimizing Organizational Protective Arrangements. The following requirements must be set: operating instructions (including avoidance of human errors, in the initial filling and in the event of trouble); qualified personnel; regular training; cleaning and maintenance permits; safe infrastructure (energy supplies, water reservoir, fire protection, waste disposal); and practices of alarm and accident prevention plans.

Avoiding Hazard Activation: Maintaining Primary Safety (First Safety Barrier). The leak-tightness of the plant (tank, piping, equipment, feeding devices, seals) must be continuously monitored. The following protective goals are important:

– Equipment to be designed for pressure, temperature, and other stresses
– Compatibility to be preserved between equipment materials and the stored substance
– Confusion of substances to be avoided (control of substances delivered)
– Materials to be sufficiently resistant to or protected from weathering or other external influences
– Protective equipment to be reliable (redundant, e.g., over-filling protective devices LS^+A^+ and level indicators LIA^+), fail-safe, or self-monitoring
– Alarms and monitors to be provided
– Automatic leak-testing to be provided at separable connections
– Protection to be provided against heat, fire, and cold
– Adequate grounding to be provided
– Protection to be provided against mechanical action from outside, e.g., guide planks
– Arrangement of the installations to be clear and understandable
– Filling systems to be situated outside the storage area
– Human errors to be reduced by organizational measures (operating instructions), e.g., rules for acknowledgment action taken, and by technical measures (e.g., over-filling safety devices with automatic disconnection LS^+A^+)
– Parts subject to wear (e.g., hoses) to be replaced in good time
– Safety equipment (e.g., over-filling safety devices) to be given regular operational tests with appropriate documentation
– Regular leakage checks with appropriate documentation to be carried out
– Periodic tests to be carried out on vessels, lines, hoses, devices for avoiding electrostatic charging, and for protection from lightning and fire

Limiting the Effects of Malfunctions (Second Safety Barrier). Malfunctions can be detected early by regular monitoring (e.g., patrols). The following protective measures can be suitable:

In store rooms (housing), regular monitoring to be supplemented by automatic early warning equipment (e.g., gas warning devices), optionally with suction into a destruction system.

Components to be designed according to the "equal safety" principle (structures of the same strength) and "leak before break": fracture of a pipe connection and catastrophic failure is then impossible, and need not be included in the considerations.

Emergency shutdown systems with quick-acting gate valves to be applied when transport tanks roll away, and optionally automatically effective in case of fire.

Emergency nitrogen and power supplies to be available if the fail-safe principle is not used.

Pipe-break safety devices or quick-acting gate valves to be incorporated in lines that convey liquid.

Quick-separation systems to be used in ship reloading.

Full-hose systems to be used at reloading or filling stations.

In connection with filling with hoses or articulated arms: quick-acting fittings to be used on both sides, in above-ground installation of tanks for combustible substances in the liquid state: good ventilation to be applied; soil areas below the tanks to be liquid-tight and drained by a safe route.

Tanks to be installed in accordance with the properties of substances, e.g., very toxic gases in the liquid state in collecting spaces, double-walled tanks with leak monitoring, or as single-walled accommodation with suction; very-low-temperature storage with collecting space for

toxic and combustible substances; as a rule, above-ground installation in the open air is best with regard to safety and cost, since the tanks can be monitored and maintained in the best possible way throughout their life.

Electrical and mechanical explosion protection to be provided.

In the case of danger to water sources, arrangements to be made for the collection of leaks (e.g., collecting spaces or double-walled tanks with leak monitoring).

No gully holes and ignition sources to be present in the protected zone, especially for separable connections.

Water sprinkling to be provided against the effect of solar radiation.

Safety valves to have a safe discharge line.

Possibility of covering the collecting space with foam or, in the case of combustible substances, filling the collecting space, e.g., with gravel.

For confined liquid volumes, e.g., in pipelines, relief valves to be present, in the case of toxic substances with optional downstream flash vessels and upstream bursting disks and buffer vessels.

Fire protection plan to be coordinated, e.g., sprinkling or flooding with water; water sprinkling by the works fire department, but only when the heat is exclusively radiant; protective gap; protective wall; fire insulation; insulation or soil cover. For installation above ground with water sprinkling, a protected extinguishing agent supply and fire protection equipment to be provided; for remote sites without continuous monitoring, optional water sprinkling or flooding with fusible fire safety device and automatic response; amounts of water sprinkling must be laid down as a function of tank size and type; for large spherical tanks ($>1000\,\mathrm{m}^3$), sprinkling densities of $\geq 100\ \mathrm{L\,m^{-2}\,h^{-1}}$ are sufficient.

Measures to be provided against fire under a tank and spontaneous combustion.

Personal safety equipment to be provided.

Alarm and accident prevention plans to be drawn up.

The fire protection plan in large works complexes with corresponding infrastructure includes: active explosion protection, qualified operators always present, specially trained works fire department always available, access to the basic pieces of equipment by agreement with the fire department for cooling and, if the need arises, for extinguishing, stock of water always available, maintenance, preventive maintenance, protected energy supplies.

Before commissioning, the safety plan of the plant is to be checked (plant monitoring). The important aspects are the following: substance data, piping and instrumentation flow charts, space-assignment plan, notice of approval, and, if occasion arises, safety analysis and operating instructions.

The acceptance inspection is concerned with operation according to the regulations and possible disturbance of this operation.

The conformity test is based on the observance of the applicable safety regulations. It assumes that there are appropriate vessels, piping, fittings, pressure generators, warning, alarm, and safety equipment, as well as seals, in accordance with the documentation used for checking of manufacturers' specifications as well as the piping and instrumentation flow charts. In the space-assignment test, the following considerations have to be assessed: fire protection, explosion protection including electrostatic charging, health protection, water protection, and infrastructure.

Requirements and design of the safety equipment are based on the process-engineering relationships, the characteristic quantities for safety engineering (properties of the substances), and the local conditions, e.g., safe discharge.

An operational test is to be made of the warning, alarm, and safety equipment. Appropriate documentation on the plant, based on the tests carried out, is to be drawn up.

The special conditions to be taken into account for individual cases, e.g., installation in a water protection area or in the neighborhood of sensitive equipment outside the works, must also be subjected to appraisal in the storage plan. In this connection, the fourth safety barrier is of decisive importance.

In some countries, detailed regulations exist on the handling and storage of dangerous substances. In Germany, the *Technische Regeln für Gefahrstoffe* (TRGS) incorporate the guidelines of the European Community, especially on the classification, packing, and labeling of dangerous industrial substances according to the level of technology employed.

6.4.2. Tanks [91,92,96–102]

In almost every branch of industry tanks are used worldwide for the storage of a variety of liquids, while bulk materials and silage fodder are stored in silos. Tanks are mostly made of ferritic steels, but also of high-grade steels, nonferrous metals, and plastics, e.g., glass-reinforced plastics (GRP). For economic reasons, ferritic sheets with cladding of high-grade steel or nonferrous metal are frequently used in tank construction. Good alternatives are ferritic steel tanks with plastic internal coatings, rubber linings, enameling, and internal coverings applied by means of vacuum (between covering and steel) to the supporting walls. Depending on the construction, it is normal to refer to flat-bottomed tanks (up to more than 100 m in diameter), cubic tanks, cylindrical tanks, double-walled tanks, double-bottomed tanks, and spherical tanks (spherical containers). Another characteristic is the permissible over-pressure, e.g., quasi-pressureless tanks ($p < 10$ kPa) detonation-resistant tanks (these may deform plastically in an explosion, but not develop leaks), and tanks with internal over-pressure ($p > 10$ kPa). For the storage of large quantities of gases liquefied under high pressure, spherical tanks (spherical containers) are preferable, which rest on legs, columns, or eggcup-shaped bases. Flat-bottomed tanks are mostly made with a fixed roof; above ca. 60 m diameter they are built as floating-roof tanks for economic reasons. For the storage of gases liquefied at low temperature (e.g., ammonia, oxygen, nitrogen, argon), the tanks are built with ca. 1.5 m thick special insulation and for permissible operating temperatures down to $-200\,^{\circ}$C or below. For substances that are not pumpable at ambient temperature, the tanks are provided with direct or indirect heating. The usual tank equipment includes: liquid-level indicators, over-filling safety devices, air-inlet and air-removal connections, gas displacement connections, filling and withdrawal connections with shut-offs. For the storage of combustible liquids with flash point $< 55\,^{\circ}$C, the tanks must be earthed and have flame arrestors in the respirator lines. In the case of flat-bottomed tanks for combustible liquids, the weld seam between cylinder and roof must be fabricated as a rated-rupture seam, so that with an inadmissible over-pressure only the roof tears off, and the stored liquid remains in the tank. The tanks are erected, preferably above ground (simple checking of corrosion damage and gas-tightness from outside as well as better accessibility during cleaning, repair, and alteration work), standing vertically or horizontally on stable concrete foundations. In the case of tanks erected above ground, catwalks, stairs, piping, and similar equipment must be so arranged that if there are changes of length as a result of temperature changes or tank settlements, they exert no inadmissible additional forces on the tanks.

Tanks for combustible and water-polluting liquids must be erected within bund walls. Flat-bottomed tanks for water-polluting liquids must be so erected or equipped that leakages in the bottom of the tank can be detected reliably and quickly. This can be achieved, e.g., by:

1) Erection on continuous concrete foundations with plastic or metal foil separating layers or the detector of a leak-detection system between the tank bottoms and the foundations
2) Erection on strip footings
3) Double-bottomed tanks with an inspection hole or leak-detection device

In Germany, steel tanks for the underground storage of water-polluting liquids must be double-walled and the leak-tightness of the interspace must be monitored by a suitable leak-detection device. In the case of underground steel tanks, the use of a cathodic corrosion protection system is advisable. For reasons of explosion-proofness and environmental protection, newly erected tanks are increasingly operated closed, i.e., with no air admission to the atmosphere and with inert gas blanketing (e.g., nitrogen).

Depending on the properties and the amount of stored liquid, the tanks are subject in many countries to national regulations for construction and equipment as well as for the environment, in particular for the protection of water sources. The detailed requirements regarding tank construction, equipment, erection, and testing contained in these regulations and in technical rules and standards associated with them are on the whole comparable as far as above-ground storage is concerned.

Tanks in operation must be tested at regular intervals in accordance with the national regulations by experts recognized by the authorities.

These experts are personally responsible for the operational safety of the tanks tested. Testing intervals are determined by the requirements of the authorities, or by the experience of the operator or builder. Testing must cover the whole tank structure, including all associated equipment. After being taken out of service, the tanks must be cleaned in a professional and environmentally acceptable way, and disposed of likewise.

7. Pipelines

7.1. Types of Pipeline

Pipelines transport and distribute substances in bulk, and are used for a variety of purposes in industry and technology. Their design specifications, layout, and operation are therefore covered by a range of technical and legal codes and standards.

Pipelines can be used as transport systems between two points (line systems), or as network systems for transport and distribution. This applies for long-distance pipelines and intra-plant systems. Typical applications for pipeline systems are for oil, gas, or water transport over long distances. Typical networks are intra- company distribution systems, communal water supply or sewerage systems, and airport fueling lines.

Pipeline systems should always be viewed as a whole. This holistic view of the transport line or network system should include the plant and facilities involved at both ends of the pipeline (Fig. 9), such as tanker ships, rail tank wagons, or road tank lorries. At the input end this may also include the source (e.g., the oil well) where this feeds into the pipeline, either directly or via a collecting tank. At the output end there may be tankage and transport plants, as well as user facilities (filling and transfer plant). The pipeline also includes all fittings, pumps valves, etc. along its length.

Pipeline systems can be laid overground or underground, or as a mixture of both. They are used to supply substances, or to remove unwanted substances (notably sewage). It is important to distinguish between pressure pipelines and gravity pipelines. Gravity pipelines are usually used only for the transport of water and sewage.

Pipelines are used to transport and distribute fluids such as oil and its derivatives, water, sewage, brine, and fluids for production, such as natural gas, hydrogen, acetylene, as well as suspensions of fine-grained solids such as cement, coal, ore, or sulfur. It is important to distinguish between flammable and nonflammable substances, since construction and operating requirements differ considerably between these.

Figure 9. Components of a pipeline system

The numerous possibilities are covered by extensive technical codes, standards, and laws, and the relevant national requirements must be taken into consideration when applying for operating licenses.

7.2. Requirements for Pipeline Systems

Pipeline systems must meet two basic requirements:

1) They must be designed for continuous operation, to ensure supply or removal of the substances involved (which is in the interests of the operators).
2) To obtain permission to operate a pipeline, whether for long-distance transport or for intra-plant operation, it must be shown that the construction and mode of operation exclude the possibility of uncontrolled release of substances into the environment during normal operation, and in the event of damage or disturbances. This requires a redundant safety system, both to protect public safety

(avoiding fires and explosions) and to pollution of soil, ground and surface waters.

The redundant safety system consists of two barriers. The primary barrier is that directly enclosing the substances, with all safety and auxiliary fittings. The secondary barrier serves to contain substances released in the event of damage or disturbance, and also any unavoidable leak and drip losses. This barrier is generally designed as a leakproof system with appropriate safety features and warning systems. Special attention needs to be paid to the transfer points at both ends of the pipeline system, since these represent weak points. This is particularly important for systems involving the discharging or loading of ships.

Extensive technical and operating requirements have been introduced, aimed at preventing unacceptable environmental damage. It is important to establish the substances which are to be transported by a system and the volumes involved, since this influences the choice of materials for the primary and secondary barriers, as well as the range of possible environmental pollution.

The toxic properties of transported substances are of vital importance. The greater the potential threats posed by these substances to the environment, the more care needs to be taken in the design and operation of the pipeline.

In addition to direct toxic effects of substances, whether to humans or more generally in the environment, other environmental effects may also need to be taken into account. Natural gas, for example, is toxic only to the extent that it carries traces of substances such as the carcinogen benzene. However, if released underground it can lead to the displacement of oxygen, with adverse effects on roots and soil microorganisms. Accompanying changes in soil conditions such as pH and redox potentials can also lead to the mobilization of heavy metals.

7.3. Design and Operation

7.3.1. Routing

A well-considered route for a pipeline can go a long way toward meeting the safety requirements for the system. This applies to both external influences on the pipeline and the effects of the pipeline on its surroundings. It is important, for example, to avoid heavily populated areas, areas of importance for water resource management, and mining areas. Where this is not possible special precautions must be taken.

Where roads or railways cross a pipeline, in addition to soil pressure it is subject to further static and dynamic loads from passing vehicles. If the soil cover is less than 1.5 m the traffic loads dominate. For cross-country pipes under railway embankments or paved roads, it is possible to calculate soil pressures and traffic loads, and hence the loads on the pipeline. The additional loads must be taken into account when determining the dimensions and properties of the pipes; special measures may be necessary.

Local conditions and climate can be particularly important for safety. In cold climates it is necessary to protect the pipeline against frost, and to elevate it on stands to prevent it from sinking and breaking during thaws. In areas subject to earthquakes the bearings must allow compensation for horizontal and vertical displacements to avoid deformation.

7.3.2. Pipeline Design

Line or network pipeline systems consist of various elements:

Pipes
Pumps
Shut-off devices (valves, stopcocks, slide gates)
Fittings
Purging cocks (for gas lines)
Condensation traps
Monitoring systems
Expansion joints

A pipeline system viewed as a whole should always be designed as a double-barrier system, capable of being monitored and repaired. The primary barrier with all its elements encapsulates the transported substance. Its freedom from leaks depends mainly on the materials used in its construction in relation to the mechanical loads to which it is subjected, and the chemical properties of the transported substances. Unavoidable losses (drip leaks at pumps, valves, and gates),

should also be contained by a second, physical barrier.

Wherever possible, there should be a continuous secondary barrier for the entire pipeline system, in the form of jacket pipes, collecting basins, and channels. In some cases this is not possible (e.g., because it would impede cathodic corrosion protection, or because differential expansion of the pipe and outer jacket threaten the system). The secondary barrier can then only consist of intensive organizational and operative back-up measures: shorter inspection periods; shorter distances between shut-off points to limit possible losses; more elaborate provisions for leak detection; continual remote monitoring of the pipeline system (both internally and externally); equipment for tackling emergency events and catastrophes; contingency plans, etc.

Such precautions are particularly important in endangered areas. Where there are threats of subsidence, it is important to carry out regular geodesic measurements along the route, and to measure the pipes for possible stretching. In densely populated areas and in important water catchment areas, the following safety measures are necessary:

– Higher specifications on the pipelines (design, materials, testing); additional supervision during pipe-laying
– Installation of additional measuring points to monitor cathodic corrosion protection
– Arrangement of shut-off fittings to limit losses
– Groundwater monitoring wells or local use of leak detectors
– Construction of safety embankments
– Laying warning bands above the overhead transmission line
– Special marking for the routes of cross-country lines
– Monitoring the route at short intervals
– Protection measures or adjacent installations

A frequent cause of incidents is damage due to external causes, e.g., excavation work. It is therefore important to provide underground pipelines with a suitable cover. For the Transalpine (TAL) Pipeline, which passes Lake Constance on its way from Genoa to Ingolstadt, the city of Stuttgart included an ozonization system in the purification plant for the water it draws from the lake, in order to be able to tackle oil leakages effectively.

7.3.3. Materials

The safety of the pipeline is affected to a considerable degree by the properties of the materials used in its construction and by quality assurance during pipe production. The measures adopted are continually being improved, e.g., better steel quality through continuous casting, secondary metallurgy, and thermomechanical rolling; improved quality control documentation (quality planning and monitoring); use of computer-aided production methods and optimum nondestructive testing procedures.

Further development of raw materials has resulted in the use of thermomechanical rolled steels and the reduction of sulfur and phosphorus levels.

When selecting and dimensioning the materials, the following criteria are important:

– Amount per unit time
– Internal pressure [constant operating pressure, shock waves (hammering), pulsating stress]
– External pressure (soil and traffic loads, bending loads)
– Temperature
– Internal and external corrosion

Selection of raw materials depends on the substances to be transported (Table 4).

7.3.4. Pipe Laying

Transport and Storage. Damage to pipes and their insulation can be avoided by suitable transport, careful loading and unloading, and proper interim storage. By training and informing personnel, careful supervision of work, and spot checks, it is possible to reduce the frequency of errors, and to detect those which do occur in time to take counter-measures.

Welding. Before welding begins in situ, it is important to check that pipes comply with delivery specifications. Only permitted filler materials may be used. Random nondestructive tests must be carried out on welded joints along the

finished pipeline section (ultrasound, irradiation, or both in combination).

Table 4. Selection of raw materials

Substance group	Special properties	Materials usually used
Water/wastewater	no special requirements (exception: corrosive water)	steel, earthenware, concrete
Gases	high mechanical strength at all pressures; resistance to corrosion by sulfur compounds and humidity in the gas	steel
Oil	high requirements for mechanical strength and expansion; high temperature stability	steel
Chemicals	high resistance to internal corrosion; high requirements for tensile strength and temperature stability	steel, copper, special alloys
Solids in suspension	high resistance to mechanical scouring; high mechanical strength	steel

Installation. In underground pipeline systems, the pipe trench and its floor must be examined before the pipe is laid. The trench must be deep enough to allow the necessary cover over the pipe, and it must be possible to install the pipe in the trench without damaging the jacket. The trench floor requires special attention to ensure that the pipe is not damaged or subjected to impermissible bending loads. The pipeline must be bedded on sand, and a compactible material must be used for filling in the trench.

7.3.5. Operation

To ensure that the pipeline transports substances at the desired rate and with constant quality, a number of measures are necessary; these depend on the necessary safety provisions, on the mode of operation, and on local conditions.

General Safety Measures. Appropriate safety equipment must be provided for all plant. The safe operation of a pipeline requires trained personnel. Organization and communication are particularly important, especially when an alarm is raised or in the event of catastrophes.

Control. The most important process information parameters, which must be continually passed to the operations center (including during interruptions), are pressure, pressure flow, volume, density, and temperature. Updates on the current state of all fittings, such as pumps, gates, relief systems, and other plant, must be passed to the operations center, together with monitoring data, in particular for the detection and location of leaks and for levels of corrosion.

In pressure pipelines, monitoring the line pressure is important. Changes in pressure can give rise to pressure waves or shock waves (hammering) which can destroy the pipeline; it is necessary to ensure continuous monitoring of shut-off valves, pressure-release devices, and safety valves.

Provisions must also be made to precisely detect, quantify, and localize losses along a pipeline due either to damage or to leaks developing under normal operating conditions. Methods are available which make use either of changes in pressure (pressure-drop or shock-wave methods) or the measurement of mass. Gradual leaks can be monitored during interruptions (pressure – temperature, pressure difference, pressure – volume methods) or during operation (leak-detection rabbits, drains, or cables).

Special rabbits or pigs can be used to identify precisely the nature, location, and size of safety threats. Distortion, corrosion, and cracks can also be identified by ultrasound, magnetic fringing flux, and high-frequency and impulse eddy current methods.

It is also important to monitor safety along the route of the pipeline, by patrols or aerial observation.

Maintenance and Repair. Regular inspection and repair of defective components serves both general safety and the operability of the pipeline systems. In addition to routine inspections on the basis of a servicing plan, a general inspection of all functions should be carried out at specific intervals (usually annually).

7.4. Incidents

No statistics on incidents are available which cover all pipeline systems and all fields of appli-

cation. In Western Europe, detailed data has been published regularly since the early 1970s by CONCAWE (oil companies' European organization for environmental and health protection) for 65 operators of cross- country oil pipelines.

There were 14 oil spillage incidents in 1991 (4 in 1990 and an annual average of 13.3 since 1971). Of these, 12 were from pipelines and 2 from pumpstations (Table 5). All incidents required cleaning up operations. The level of soil contamination caused by the incidents varied: 2 caused no contamination; 5 were classified as causing slight contamination ($< 1000\,m^2$ soil affected); 7 were classified as serious. Two petrol/diesel incidents polluted watercourses.

Table 5. Causes and numbers of incidents since 1971

	1991	Average 1971 – 91
Mechanical failure	7	3.3
Operation		0.9
Corrosion	4	4.4
Natural disaster		0.6
Damage by others	3	4.1
Total	14	13.3

The net oil loss into the environment in 1991 was $902\,m^3$ (0.00015 % of the total volume transported). The gross loss was $1346\,m^3$ (0.00023 %). A total of $444\,m^3$ (33 % of the gross loss) was recoverable.

7.5. Economic Aspects

Pipeline systems provide continuous transport and distribution of substances in bulk. Features of pipelines, in comparison with other means of transport, are low transport costs (low energy requirements), virtually loss-free transport, high operational reliability, and ease of maintenance. Pipeline systems allow greater flexibility in the choice of sites for industrial development, since the raw materials and fuels can be transported to the location, rather than the plant having to be located near the source of the raw material. Pipelines can thus be of considerable economic advantage to a country or region, since they allow the continued use of existing industrial infrastructures.

Advantages over other means of transport include shorter routes, which are usually more direct, fully automated operation (with correspondingly low costs for operation and personnel), as well as reduced environmental impact. The distances involved must be suitably large, and demand should be evenly distributed over the year, to warrant the relatively large investment costs involved.

No global summary is available for all bulk pipeline systems for oil and its derivatives, gas, water, wastewater, solids, and chemicals. In Western Europe, companies operate some 210 different service pipelines which, at the end of 1991, had a combined length of 21 000 km. In $1991, 593 \times 10^6\,m^3$ of crude oil and refined products was transported, ca. 8 % more than in 1990, most of the increase being in crude oil. This gives some idea of the importance of pipelines for the economy as a whole.

8. Future Developments

With the liberalization of shipments, world freight traffic continues to increase. In Europe this tendency is reinforced by the implementation of the Common Internal Market and by the opening up of Eastern Europe.

In the past, the transport of dangerous goods developed in parallel with freight traffic as a whole. In Germany at present about 15 % of freight volume involves the transport of dangerous goods; in the European Community the proportion is similar [103, 104]. The proportion of road transport has grown steadily, whereas rail and inland waterway transport have been pushed back (Fig. 10).

Figure 10. Transport of dangerous goods in the Federal Republic of Germany
a) Road; b) Rail; c) Ship (inland waterway); d) Total

Also to be expected in future are further increases in the transport of dangerous goods, in haulage distances, and in traffic across frontiers,

and a growth in the proportion of road transport of dangerous goods (Fig. 10).

These developments entail an inevitable increase in environmental pollution as a result of total pollutant emissions from the operation of transport systems, even if the emissions in relation to distance covered can be reduced. In addition there are waste disposal problems, such as the cleaning of freight containers. In Germany, the release of dangerous goods in traffic accidents and from storage has not increased to the same extent as the total freight traffic volume. Nevertheless, the aim must be to prevent any release of dangerous materials into the environment.

Long-distance road transport has the greatest danger potential. Figure 11, for transport of water-endangering materials in Germany, shows that long-distance road transport accounts for more than seven times as many accidents, relative to transport volume, as rail transport. The volume of water-endangering materials leaked and not recovered, relative to the transport volume, is almost three times as large. Inland waterway transport has lower accident figures than road transport, but the amount of water-endangering materials entering the environment as a result is distinctly higher than for the other carriers.

Figure 11. Potential risk of carriers for water-polluting substances

Not all shipments of dangerous goods can be transferred to rail, for capacity reasons. Besides, it may be preferable not to send a particular shipment of dangerous goods by rail if the route leads through districts that are densely populated or particularly worthy of protection, if road transport permits a harmless detour. Preconditions for a greater transfer of shipments of dangerous materials to rail are freight traffic centers on the margins of the more densely populated zones, as provided in the German Railroads plan [105], and an area-wide presence of the railroad in short-haul transport.

The existing waterways in Germany could absorb an additional freight transport volume of about 20 % [106], but the new construction or development of waterways, e.g., as investigated for the Elbe, is problematic for ecological reasons [107].

8.1. International Harmonization of Dangerous Goods Regulations

Although concern about the safety of shipments of dangerous goods has led to international agreements, questions of environmental damage have so far played rather a minor role.

On 1 January 1995 criteria for the classification of environmentally relevant substances were introduced for the first time into the international agreements on cross-border transport of hazardous materials existing since 1957 [108, 109], taking into consideration the expert recommendations of the UN.

The EU has adopted these regulations in framework directives, which remain to be introduced by the Member States. From 1 January 1997 onwards the directives will also apply to intrastate transport in the EU. Up to now the criteria deal only with aspects of water pollution; hazards to soil and air are not included.

Furthermore, there is a need for action regarding harmonization of the classification systems of the individual transport routes. Thus it is possible that goods transported by ship are classified, packaged, and labeled differently to those carried by rail or road.

In addition a uniform classification system in the field of transport should be harmonized with the classification schemes in other legal areas. Such a harmonization has already been commissioned:

In 1992 the Conference for Environment and Development (UNCED) adopted Agenda 21 in which the signatories commit themselves in

Chapter 19 to work out an internationally coordinated classification system.

8.2. Transport Avoidance and Regulatory Measures

Previous national measures, like international ones, were aimed at making the transport of dangerous goods safer: the transport volume itself was not the subject of regulation. The safest strategy for dangerous goods, however, is undoubtedly one in which they are not transported at all. Shipments of dangerous goods can become superfluous, e.g., by abandoning products involving the use of dangerous substances, or by rearranging production processes.

The best-known example of an international environmental protection agreement that resulted, as a side effect, in a rearrangement of production processes and a withdrawal of products, is the 1987 Montreal Agreement for the protection of the ozone layer. The prohibition of the production and use of specific chlorofluorocarbons that, aside from their action on the stratospheric ozone layer, are also water-endangering, has required rearrangements of production [110].

Conversion of the Basel agreement for controlling the export of wastes across frontiers to an EC statutory regulation [111] is likely to lead to an increase in the transport of wastes. This anomaly arises from the provisions in the statutory regulation, for the acceptance of new lists and reclassification and deletion of existing lists, graded according to the degree of surveillance, the vagueness of the definition of waste, and the tendency to liberalization in the worldwide movement of goods under the influence of rising costs of local waste disposal.

Aside from regulatory means, incentives for transport avoidance, and the traffic deflection, can also be achieved by economic instruments. It has been estimated that consistent application of the "polluter pays principle", which requires internationalization of external costs, would add $46\times10^9 - 250\times10^9$ DM per year to transportation costs in the federal states of pre-unification Germany. These are low estimates as they take no account of important external costs such as the effects of climatic change [112, 113].

In many cases, external costs can not be allocated unequivocally to the polluter. In addition, subsequent internalization of external costs is impossible if irreversible environmental damage has occurred [112].

The level of external costs shows that it would be possible, e.g., by a general tax on the transport of dangerous goods, to create inducements to rearrange production and contribute to transport avoidance.

A first step in this direction is represented by a proposed EC directive in which the external costs would be charged to heavy commercial vehicles (environmental loads are expressly mentioned as external costs) [114].

1. Origin of Waste

In Germany quantities of waste generated must be determined according to the German Environmental Statistics Act. The Federal Statistical Service (StBA) [1] publishes two summaries:

1) Statistics on public waste disposal
2) Statistics on waste disposal in production plants and hospitals

The two figures are based on different principles. In the StBA waste balance, waste disposal data are compared with waste production data. Duplicate entries are removed, so that a net balance is presented without substances passed on to reprocessing businesses and the scrap trade.

Wastes produced in 1990 amounted to some 300×10^6 t, which broke down as follows:

Sewage sludge	2 %
Hazardous waste	3 %
Household waste	15 %
Industrial waste	39 %
Construction waste	41 %

Construction wastes are the major component. The net contribution of hazardous wastes, according to the waste balance, is ca. 10×10^6 t/a and the gross amount ca. 15×10^6 t/a.

The StBA statistics have been criticized on the following grounds [2]:

1) The results appear too late
2) The figures are not adequately broken down
3) The data are not in accord with present-day constraints on waste management
4) Waste-prevention and reclamation activities are not covered by the statistics
5) The StBA waste balances are incomplete

The same problems exist throughout the field of waste statistics.

Figure 1. Composition of residential waste in 1979 – 1980 (A) and 1985 (B) (in wt %) [4, p. 17]

1.1. Municipal Waste

Table 1 summarizes the quantities of household, commercial, institutional, and bulky wastes collected in public waste-disposal activities [3].

Household waste includes all wastes and residues from chiefly private households, which are regularly collected, transported, and disposed of in the interest of keeping dwellings clean.

Table 1. Quantities of residential, commercial, institutional, and bulky waste colleted in public waste-disposal activities [3]

Italy	249	301	6 270	18 729
Portugal	167	231		
Austria	216	228	8 670	20 906

This includes:

1) Food wastes and kitchen wastes if not carried away with sewage
2) Waste paper
3) Packaging materials from consumer goods
4) Heating residues (e.g., ashes)
5) Small objects that have become unusable
6) Broken crockery, glass, porcelain, etc.

When countries are ranked in terms of waste generated per inhabitant, Germany falls in the middle part of the list (Table 2). In interpreting these figures, however, note that usage of the word “waste” differs from country to country.

Figure 1 ([4, p. 17]) shows the makeup of residential waste based on the German federal household waste analysis in 1979 – 1980 and 1985. Some characteristics of household waste are listed in the following [1]:

Figure 2. Waste composition over time [4, p. 18]

Lower heating value, kJ/kg	6000 – 10 000
Combustile content, wt %	45
Ash (inerts), wt %	25
Water, wt %	30
Merchant iron (rel. to total wt.), wt %	4 – 5
Bulk density, kg/m^3: loose	90 – 120
compacted (landfill vehicle)	350 – 550
Organic matter as TOC, wt %, dry basis	30 – 70
Inorganic matter, wt %, dry basis	30 – 70
Carbon, wt %, dry basis	10 – 50
Hydrogen, wt %, dry basis	4 – 5
Nitrogen, wt %, dry basis	1 – 2
Chlorine, wt %, dry basis	0.1 – 1.0
Sulfur, wt %, dry basis	0.03 – 0.5
Lead, g/kg, dry basis	0.7 – 2.0
Cadmium, g/kg, dry basis	0.01 – 0.05
Mercury, g/kg, dry basis	0.001 – 0.05

Figure 2 shows how the composition of residential waste has changed over the past decades.

Specific waste volume (i.e., volume per inhabitant) has increased much more rapidly than specific waste weight since 1950 (Fig. 3). From about 1900 until after World War II, the amount of waste generated – both the weight and the volume per inhabitant and year – remained almost constant. Marked decreases were recorded during the two World Wars. With the coming of prosperity starting around 1950, the Länder of the pre-unification Federal Republic showed a continuous increase in quantity of waste produced, whereby the specific weight increased less rapidly than the specific volume. The reasons for this discrepancy were the shift from fires in single-room stoves to central heating and the increased use of packaging, plastics, and printed materials. In the former German Democratic Republic, the weight and volume curves ran nearly parallel, even after World War II. The situation in the new eastern Länder changed after reunification. The per capita amount of waste produced was for a time much greater than in the western Länder (pent-up demand), but now seems to be swinging back into line with the western Länder. The use of combustible wastes in stoves and furnaces is declining steadily as oil- and gas-fired central and district heating systems are established, while the quantities of packaging and printed paper waste are similar.

As to the quantities of valuable products identified in German residential waste and recovered by sorting, figures for individual substance classes are rough, and the balances do not work out exactly for all substances.

The quantities available and recovery rates of Table 3 were estimated on the basis of the German household waste analysis of 1985, which found 14×10^6 t of residential waste to be disposed of, together with a scenario and an adjustment for 1993 packaging statistics [6].

Table 3. Forecast recovery of values from household waste [a] in Germany, 1993 [6]

Substance class	Household waste, t	Quantity disposed of, t	Quantity recovered, t	Recovery rate [d], %
Paper, paperboard [b]	7 500 000	3 700 000	3 800 000	50.6
Glass	3 700 000	1 300 000	2 400 000	63.2
Aluminum	130 000	120 000	10 000	8.0
Tinplate	700 000	450 000	250 000	35.7
Textiles	600 000	325 000	275 000	45.8
Plastics	1 400 000	1 100 000	300 000	21.4
Vegetable material	11 800 000	10 300 000	1 600 000	13.6
Residual waste [c]	3 100 000	3 100 000		
Total	29 030 000	20 395 000	8 635 000	29.8

[a] Waste from private households, excluding bulky and commercial waste. [b] Packaging paper and graphic paper. [c] Fine trash mineral material, mineral composites, etc. [d] Not identical to rates of German Packaging Regulation.

Figure 3. Specific waste volume and weight over time (1900 – 1945 for Germany, later for pre-unification Federal Republic) [4, p. 18]

Commercial waste has increased faster than household waste (see Fig. 4). Biowaste includes organic, compostable constituents of residential waste that are collected separately and composted. Problem wastes (pollutants) contained in residential waste are small quantities of substances that cause harm to humans, the environment, and facilities. Such substances include solvents, paints, batteries, medications, pesticides, and household chemicals.

Bulky waste from households belongs to household waste and is related to it, differing only in size. The boundary between residential and bulky waste is fluid, depending chiefly on the size of the collection containers. Bulky waste, even after size reduction, generally cannot be collected along with the ordinary containers because of its bulky nature.

According to BILITEWSKI, the factors governing production of bulky waste include the following [5]:

1) Size of the municipality (area and population)
2) Fraction of commercial waste collected together with residential waste
3) Consumption and lifestyle patterns, standard of living, economic status
4) Commercial, social and geographic structure
5) System used for residential waste collection: container size and type (container volume per inhabitant and day)
6) Number of persons in the building from which waste is collected
7) Frequency and organization of waste collection
8) Waste producers' alternatives to ordinary waste disposal: special containers for valuable materials, self-composting, recycling yards, recycling pickups by associations, collection by private contractors
9) Fees charged for residential and bulky waste collection

Garden and Park Waste. Garden waste is generated in gardens, parks, and cemeteries and also on streets (e.g., leaves, branches, grass, and clippings) and is commonly not removed by waste collection. It poses a problem for treatment facilities handling household waste, because it arises periodically and in large quan-

Figure 4. Quantity of waste produced by a large city, broken down into household/bulky waste and commercial waste [4, p. 18],

tities. Where garden waste cannot be recycled by composting on the spot, it is usually removed on an individual basis.

Market Waste. Street waste consists of

1) Material washed and rubbed off street surfaces plus rubber from vehicle tires
2) Leaves and branches dropped by streetside trees
3) Material scattered for winter traction
4) Dust emitted by private and commercial furnaces
5) Litter

Other wastes include trash, cans, waste paper, leaf waste, weeds, and solids retained in storm sewerage intakes (catch basin sludge). This material consists chiefly of street sweepings carried into the intakes by rain or sprayed water.

Market wastes are included in the category of commercial waste, but because of special market rules some such material is collected by municipal street cleaning. The same applies to waste from public markets (e.g., vegetable and leaf waste, packaging, and shipping materials such as wooden crates and pallets).

Construction Waste. Rubble and excavated soil are commercial wastes that are not generally collected together with other wastes, but they may represent a large fraction of the total waste produced in a region (depending on construction activitiy).

Rubble includes broken masonry, mortar residues, and concrete, and often contains metal fragments, wood, and paper waste as well. This category also includes furnace lining material, slag, sand from metal foundries, and sludges from the production of concrete, cement, mortar, and limestone sand. These wastes can be processed and recycled.

Excavated soil comprises natural soil and rock, not detrimentally modified, that is dug out or scraped off during excavation and earthmoving. If such soil is expected to contain pollutants, it must be analyzed and treated separately. Excavated soil can be used as fill or to cover other wastes in landfills.

Mixed construction site wastes are mixtures of rubble, concrete material, and excavated soil of mineral origin, as well as paper, plastics, wood, glass, ceramics, insulants, metals, and pollutants. They are generated by new construction, repair work, and renovation.

The quantities of various construction wastes are listed in Tables 4 and 5.

Table 4. Generation of construction waste in the Federal Republic of Germany , p. 45[5]

Type of waste	Amount generated ∗, 10^6 t/a	Recovery rate ∗∗, wt %
Excavated soil	170	32 (∗∗∗)
Building rubble	23	16 (60)
Pavement rubble	20	55 (90)
Construction site waste	12	0 (40)

∗ Extrapolated to 1990.

∗∗ Figures in parentheses are targets set by the German Federal Government.

∗∗∗ Uncontaminated soil should be reclaimed and should not be dumped in landfills.

Table 5. Forecast generation of construction waste in the former Democratic Republic, 1990 , p. 45[5]

Type of waste	Amount generated, 10^6 t/a	Estimated recovery rate prior to 1990, wt %
Excavated soil	5	
Pavement rubble	6 – 7	
Building rubble	5 – 6	2

Sewage Sludge. Household sewage sludge consists of a mixture of water with solids separated from wastewater in communal clarifying and treatment plants.

Because communal sewage treatment plants also handle industrial wastewaters, household sludge in the narrow sense is only produced in domestic sewage treatment systems and consists chiefly of human excrement.

The sludge retained in mechanical wastewater clarifiers is referred to as clarifier sludge. The sludge from trickling filters is called trickling filter sludge; that from activated-sludge processes is called activated sludge.

Sludge from a modern municipal treatment plant with a biological stage consists of a mixture of clarifier and activated sludges.

There are two forms of sludge:

1) Fresh residential sewage sludge (fresh or raw sludge) is obtained as top or bottom sludge from clarifiers.
2) Digested residential sewage sludge (digested sludge) is sludge that has been subjected to an anaerobic biological process in special digesters.

An example of sewage sludge composition is given in Table 6. The content of pollutants must be considered in assessing possible applications of the sludge; its water content and heating value has to be taken into account with regard to self-sustaining combustion.

Commercial and industrial wastewaters are generated directly or indirectly in connection with the commercial objective of a company or the production of industrial goods.

These wastewaters are classified according to business size:

1) Wastewaters from small commercial operations are often released into municipal sewerage without pretreatment. They are diluted by residential wastewater in the sewers. They usually have little effect on the composition of municipal wastewater.
2) Wastewaters from larger commercial and industrial sites can crucially alter the quantity and quality of municipal wastewater. They must be allowed for in the design of municipal sewage treatment plants. These wastewaters are often pretreated in on-site clarifiers before being released into municipal sewerage.

Commercial and industrial sludges are residues from clarifying systems in industrial plants. Their composition depends on the production process as well as the treatment. They vary wide in nature, including:

1) Lime mud from neutralizers
2) Hydroxide sludge from chemical precipitation systems
3) Hair and skin scraps from tanneries
4) Sand and soil from washing of potatoes, carrots, etc.

Solids from industrial wastewaters are separated along with residential sewage sludge in municipal treatment plants. Because of their special physical or toxic properties, they interfere with utilization of the sludge. Sludges containing metal salts, cyanides, and so forth are banned for agricultural use, for example. Excess sludge from biological treatment systems in industry contain primarily dissolved organic contaminants; as far as composition is concerned, these can be equated to activated sludge from household wastewater.

1.2. Hazardous Waste

The amount of hazardous wastes produced can be determined in two ways:

1) Through triennial surveys conducted by the Federal Statistical Service on waste disposal in producing industries
2) From waste waybills used as an aid in monitoring waste transportation

Neither procedure can dependably supply exact data. Sources of error include the following:

1) When waste waybills are tabulated, duplications are often missed, because the records show hazardous wastes en route from the producer to physicochemical treatment and also individual constituents and components en route from pretreatment to landfill
2) The Federal Statistical Service surveys only cover wastes produced by operations with more than 19 employees

Waybill information was tabulated for the Federal Republic of Germany in 1984, 1985, and 1988. The quantity of hazardous waste increased in the period from 1984 to 1988. The total in 1988 was 10.2×10^6 t, including 3.3×10^6 t of hazardous wastes requiring nationwide certification [2].

Figure 5 shows quantities of hazardous waste based on the 1984, 1985, and 1988 tabulations and 1990 figures of the StBA.

Figure 5. Quantities of hazardous waste based on tabulation of waybills

Additional hazardous waste is generated by pollutants present in residential waste. Some 700 tons of hazardous wastes was collected separately in 1993.

According to the German Technical Directive on the Disposal of Hazardous Waste (TA Sonderabfall), the following treatment routes are available for hazardous wastes:

1) Physicochemical and biological treatment
2) Incineration
3) Disposal in aboveground landfills
4) Underground disposal

Annex C of the TA Abfall gives a catalog of wastes particularly subject to regulation. The only wastes listed are those from the annex of the German Waste Definition Regulation (Abfallbestimmungs-Verordnung). The catalog gives instructions on physicochemical, biological, or thermal treatment as well as disposal of various types of waste. Also included are defective intermediate and end products that may be generated by production processes.

Residual materials listed in the annex of the German Residual Material Definition Reg-

ulation (Reststoffbestimmungs-Verordnung) are not included in this catalog. A type of waste that is essentially recoverable will appear in the catalog of substances particularly subject to regulation only if a lack of reclamation options dictates that the waste has to be disposed of.

The disposal instructions apply only in cases where the reclamation test of TA Abfall, Section 1.3, gives a negative result and the waste must be disposed of pursuant to Section 1.4. The catalog of wastes particularly subject to regulation is organized along mixed lines on the basis of the properties, composition, and state of aggregation, as well as the origin of the waste class.

In this catalog, high-level sorting concepts are used to categorize waste classes in three successive, systematic levels called supergroup, group and subgroup. The decimal classification is used to identify these categories:

Supergroups	one-digit numbers
Groups	two-digit numbers
Subgroups	three-digit numbers

The five-digit numbers (waste codes) contained in the subgroups characterize the classes of waste. Every waste subject to disposal must be assigned one of these waste codes.
Example:

1	Supergroup: Wastes of plant and animal origin, wastes of refined products
17	Group: Wood wastes
17211	Subgroup: Sawdust and chips, oil-impregnated or with harmful contaminants, chiefly organic

The catalog is based on nomenclature customary in waste management. The names of supergroups, groups, and subgroups are part of the names of waste classes. They must be taken into account when determining the class of waste. When pure substance names are selected to denote a waste class, the pure substance is the waste-defining component even though the waste generally contains impurities.

In other cases, environmentally relevant properties are included in the name of a waste class, for example physical and chemical properties.
Example:

17211	Sawdust and chips, oil-impregnated or with harmful contaminants, chiefly organic
17212	Sawdust and chips, with harmful contaminants, chiefly inorganic

Some waste class names include terms such as "free of" or "without." These terms are not absolute but relate to the environmental relevance of the admixtures. Information as to origin is intended as exemplary and provides additional description of the waste class.
Example:

57801	Shredder residues (light fraction)

The regulatory relevance depends on the quantity. The waste class can be found in the catalog through a summary of supergroups, groups, and subgroups, or through an alphabetical index. If a waste can be assigned distinct waste codes, the preferred key is the one that better characterizes the waste with regard to its properties.

Columns 5 to 11 of the catalog contain disposal instructions based on experience:

CPB:	Physicochemical/biological treatment
HMV:	Municipal waste combustor
SAV:	Hazardous-waste incinerator
HMD:	Municipal waste landfill
SAD:	Hazardous-waste landfill
UTD:	Underground deposition
Others:	Special handling (for example)

When there are several disposal options, preference classes are entered in columns 5 – 10. Preference class 1 identifies the normal disposal case; preference class 2 identifies a disposal route that is also possible because of:

1) The composition of the waste
2) Special measures, for example special pretreatment of the waste or extra precautions in the disposal facility
3) Site- and plant-specific circumstances

When the disposal options rank equally, the same class number is repeated.

For waste classes where the pollutant levels can fluctuate widely, the reference under preference class 2 is to options associated with residential waste: HMV or HMD. This is the case for wastes that can be disposed of in an environmentally compatible fashion in waste-disposal facilities not covered by TA Abfall.

1.3. Future Determination of Waste Generation

Quantities of wastes produced will be determined more exactly in the future. Advances are expected through improved surveys when the new German Environmental Statistics Act comes into force and through balancing by substance from winning of raw materials through waste production.

New Environmental Statistics Act. With the promulgation of the Environmental Statistics Act (Umweltstatistikgesetz) on September 28, 1994, years of preparation and discussion of practicable waste statistics come (provisionally) to an end. The act embodies compromises between opposing viewpoints in some instances.

The material part of the new act governs surveys and data acquisition in four areas:

1) Waste management
2) Water resources
3) Air pollution abatement
4) Environmental economics

The act establishes a number of broad rules for meeting the requirements of the Federal Statistics Act (Bundesstatistikgesetz).

In deference to the federal consolidation program, the act does not take effect until January 1, 1997; in the meantime, the provisions of the 1980 Environmental Statistics Act remain in force.

The following goals are the new act:

1) Data acquisition is adapted to an increased demand for information.
2) Information will be kept more up-to-date.
3) Reporting obligations are unified so that preparation of reports will be less onerous.

The priority task now is methodological and organizational preparation for surveys.

Substance-by-Substance Balancing. If exact information about waste production is to be obtained in the future, this is possible only if individual substances are balanced from production to reclamation. This requirement is also in accord with the view of the Council of Specialists on Environmental Questions [8]. WUTTKE has presented an example of batchwise balancing for PCBs [2]. The PCB stream for 1992 is given as follows:

Accumulated domestic production in Germany was 76 000 t; imports amounted to 27 000 t. The total domestic consumption of PCBs is thus 103 000 t. Exports were 16 000 t, leaving 87 000 t in the country. This quantity was divided between open and closed application routes.

Open application in printing inks, plastics, self-copying papers, etc. accounted for ca. 25 000 t of PCBs. Open application has severely contaminated all environmental media. For example, PCBs in self-copying paper passes via residential waste into waste treatment; with old pa-per, through paper recycling, into new paper and into the wastewater of plants processing old paper. PCBs were also used in joint-sealing compounds for concrete buildings and in flame-retardant coatings for ceiling tiles, and in this way later becomes a contaminant in building rubble.

Closed application, for example in electrical capacitors and transformers and in hydraulic fluids accounted for ca. 62 000 t of PCBs. This application has led, and continues to lead, to environmental and workplace burdens all along the reclamation route, as is shown by the presence of PCBs in lubricating oil systems and in steel scrap.

Because of the ban on PCBs, more PCB-containing devices and materials are now being disposed of. But not all the PCBs produced and used are disposed of. PCBs from most open applications have already passed into the environment in dispersed form, though in part they have already been biologically degraded. Also, PCBs reach disposal facilities not just in their own form but also in devices and materials, so that the quantity of PCB waste yet to be disposed of is still thought to be large.

After 1993 and up to the year 2000 (corresponding to the term of the German Chemical Ban Regulation), the Federal Environmental Office expects ca. 340 000 t of PCB waste to be disposed of. Possible disposal routes are incineration for liquid wastes (over 130 000 t) and underground deposition for solid wastes (ca. 105 000 t).

The discrepancies result from uncertainties in the data, as would be expected given the na-

ture, quantity, and duration of PCB use, which was formerly not subject to reporting. According to the Federal Environmental Office, 20 000 t of PCB-containing wastes from the rehabilitation of buildings with concrete joint sealants containing PCBs must be disposed of. These materials, however, will not be disposed of until the year 2000; the anticipated amount for the next six years is 4000 – 5000 t.

2. Legal Aspects

2.1. Introduction

The German Recycling Act became law in the version of Bundestag Document 12/8084 and was promulgated in the autumn of 1994. It is a so-called article act. Article 1 contains the law as such, and is titled "Gesetz zur Förderung der Kreislaufwirtschaft und Sicherung der umweltverträglichen Beseitigung von Abfällen (Kreislaufwirtschafts- und Abfallgesetz – KrW/AbfG)" [Act to Promote Recycling and to Ensure the Environmentally Safe Disposal of Wastes]. Article 13 governs the coming into force of all provisions. As a rule, this occurs two years after promulgation of the act, that is, in autumn 1996. Until then, the Waste Act (Abfallgesetz) of 1986 remains in force.

As soon as the Waste Act – "Gesetz über die Vermeidung und Entsorgung von Abfällen (Abfallgesetz – AbfG)" [Act on the Avoidance and Disposal of Wastes] – took effect in 1986, the scene was set for the implementation of a waste disposal concept attuned to the times.

While it had been common to collect all wastes and dispose of them in landfills, possibly after pretreatment, the 1986 Waste Act set new priorities: avoidance of waste takes priority over waste recycling and disposal.

This objective corresponds to the principles of a modern waste management policy: The generation of wastes must be avoided in the industrial sector if possible. Any wastes produced should be recycled. Wastes that cannot be avoided or recycled must be disposed of without harm to the environment.

The Waste Act of 1986 has been expanded in significant ways, such as the authorization to issue general administrative regulations, the new provisions for the disposal of used oil, the requirement to keep certain harmful substances separate and the seller's obligation to take them back, and the possibility of setting goals for reducing the problem of waste quantities. These changes have been set forth in a series of regulations, administrative directives, and target. Important for the chemical industry in particular are the Waste Determination Regulation [Abfallbestimmungs-Verordnung], the Residual Substance Determination Regulation [Reststoffbestimmungs-Verordnung], and the Technical Directive on Wastes [TA Abfall].

In addition, it has been or still is necessary to take account of several international codes such as the EC Directives in drafting bills and regulations.

Nevertheless, waste management is confronted with problems not yet solved: In spite of all measures to avoid and recover wastes, quantities of waste continue to increase. Exporting larger amounts of waste is not a solution, since there is no guarantee for their environmentally safe disposal. The disposal of hazardous wastes poses special difficulties. Low public acceptance of new disposal facilities of this type has led to a shortage of disposal capacity.

These above aspects, the associated rises in disposal costs, and difficulties in obtaining permits under the Federal Pollution Control Act – which may be issued only for disposal of hazardous wastes under safeguards – are making hazardous waste disposal an even more serious problem for companies. At first, hazardous waste landfills had to accept all problem wastes without safeguards. Today, these landfills (such as Gerolsheim in Rhineland-Palatinate, Georgswerder in Hamburg, and Münchehagen in Lower Saxony) have become some of the most dangerous polluted sites, and so it is certain that hazardous waste disposal must be decisively improved.

This chapter therefore sets forth and discusses all principles of law relevant to the chemical industry. Waste disposal is carried out subject to the German Federal Waste Act and supplementary state laws. The regime of waste law and its fundamental concepts must therefore be explained first. The most important problem areas, such as disposal, its organization, and its financing, are then discussed against the background of the pertinent legislation.

2.2. The Recycling Act

According to the concurrent German Federal Legislation as anchored in the German Constitution, the Federal States have the right to pass their own waste disposal legislation only as long as and to the extent that the Federal Republic has not made use of its right to legislate. In the time following passage of the Federal Waste Disposal Act (Abfallbeseitigungsgesetz) in 1972, all Federal States adopted state waste management laws, sometimes amending their own prior legislation; these acts are substantially alike in that they are more or less implementing acts to the Federal Waste Act.

The Recycling Act can be applied only when the property in question is waste in the sense of the act. The concept of "waste" is therefore crucial. The meaning of this term in German Federal Law (§ 3 Sect. 1 Clause 1 KrW/AbfG) represents a conclusive rule that state and local legislation can neither narrow nor broaden. The new definition of waste, in comparison with the definition used in the 1986 Waste Act, implies a substantially broader potential applicability of waste law. In principle, all substances and objects that are not products are subject to surveillance pursuant to waste law (§ 40).

> According to § 3, waste comprises all movable property
> – That falls under the classes enumerated in Annex 1 (objective component) and
> – Whose owner is getting rid of, wishes to get rid of, or must get rid of it (subjective component)

This concept of waste corresponds to that of EC Council Directive 91/156, though the directive speaks not of "movable property" but of "substances or objects."

The definition makes it clear, that waste can only be movable property. This immediately excludes property that is not movable, such as real estate, contaminated soil before its excavation, and houses before their demolition.

The term "owner" used in the definition is legally defined by Art. 1 Letter c of EC Directive 75/242 as amended. Beyond mere possession, it also takes in the intention of exercising such possession. The term "owner" is also legally defined in § 3 Sect. 6. The owner of wastes is any natural person or corporate body having actual possession of wastes.

The definition of waste in European law, like the German definition, includes the constituent fact "get rid of" or "riddance." This term is defined by § 3 Sect. 2. This text distinguishes three cases of riddance:

1) Reclamation in the sense of Annex II B
2) Disposal in the sense of Annex II A
3) The surrender of actual possession of movable property with no further determination of purpose

"Delivery" in the sense of the first two cases means the direct handing over of the property to an entity prepared to reclaim or dispose of it. The surrender of actual possession with no further determination of purpose means the handing over of the property to persons and institutions that in turn perform treatment operations necessary for recovery or disposal, such as haulers. The third case of riddance provides that anyone who surrenders actual possession of movable property with a definite end in view, for example, sells or transports it, does not "get rid of" the property in the sense of § 3 Sect. 2.

The concept of waste has an objective component: it covers waste in the objective sense. Wastes in this sense are all movable property that fall into the classes enumerated in Annex I and whose owner must get rid of them. The waste classes correspond to the waste classes of EEC Directive 91/156. The Commission has issued the European waste catalog, filling these classes, by a decree of December 20, 1993. As a result of the enumeration principle, there can be no problems with regard to movable property falling under recycling law. The same holds for the obligation of riddance: it is defined in legislation. According to § 3 Sect. 4, the obligation of riddance exists when the movable property is no longer being used according to its originally intended purpose; if its concrete condition is such that it is suitable to endanger the welfare of the public, in particular the environment, in the present or future; and if its hazard potential can be eliminated only through an orderly and innocuous reclamation or disposal compatible with the public welfare pursuant to the provisions of this act and of regulations issued on the basis of this act. The criterion "obligation of riddance" of the objective concept of waste con-

tains normative elements. The movable property can (1) no longer be used in accordance with its original purpose – this is the case if the user can no longer employ the property according to its intended purpose, that is, objectively the property has lost its originally intended purpose. The concrete condition of the property (2) must be such that it is suitable to endanger the welfare of the public, in particular the environment, in the present or future – this suitability is to be established in accordance with objective criteria. The hazard potential (3) can be eliminated only through an orderly and innocuous reclamation or disposal compatible with the public welfare pursuant to the provisions of recycling law; this question is also answered on the basis of objective criteria.

The concept of waste has a also subjective component: it covers waste in the subjective sense. Only the property listed in the waste catalog can become waste in the subjective sense. In this way, however, no gap is created: The waste catalog contains a "cushion" criterion. The closed character of the catalog therefore does not imply the exclusion of certain property from the waste concept. As before, anything can become waste in the subjective sense. The objects or substances of the waste catalog are waste in the subjective sense if the owner gets rid of them – decisive for this is the above-stated behavior in the sense of § 3 Sect. 2 – or wishes to get rid of them. The intention to get rid of property is defined in § 3 Sect. 3. The standard distinguishes two cases: Intention to get rid of property (1) is presumed for such movable property that arises in energy conversion, manufacturing, processing, or utilization of substances or articles or in services, without the purpose of each operation being directed hereto. For property not comprised by the purpose of the operation, the intention of riddance is thus constructive; economically exploitable movable property that arises in the activities named in the act is waste in the subjective sense. The intention of riddance (2) is presumed when the original intended purpose of movable property falls away or is abandoned without a new purpose of use arising directly at its location. One can say that an intention of riddance is to be presumed if the movable property has become meaningless for the owner. In order to assess the intended purpose according to § 3 Sect. 3 Clause 1 No. 2, the view of the producer or owner is to be considered, with allowance for the normal view, according to § 3 Sect. 3 Clause 2. According to the definition of § 2 Sect. 5, "producer" means any natural person or corporate body that has performed prior operations that effect a change in the nature or the composition of these wastes. What is waste in the subjective sense, according to § 3 Section 3 Clause 2, is substantially governed by the subjective view of the producer or owner. In contrast to previous waste law, there is no separate document defining hazardous waste or wastes subject to special surveillance. According to the definition in § 3 Sect. 1, these wastes are also covered by the reference to the waste classes enumerated in Annex I.

2.3. Principles of Recycling

The first principle is that of domestic disposal. All wastes in the sense of the act, according to § 10 Sect. 3, must be disposed of within the country. Pertinent EC provisions, however, remain unaffected (Regulation on Supervision and Control of Shipments of Wastes within, into, and out of the EU; Act Implementing the Basel Convention of March 22, 1989, on the Monitoring of Cross-Border Transportation of Hazardous Wastes and Their Disposal).

According to § 4 Sect. 1, wastes are first to be avoided and only second is their material or energetic content to be recovered. This statement is in accord with the corresponding provision of the EC Framework Directive on Waste.

2.3.1. Avoidance before Recovery

The objective is made clear in § 4 Sect. 2 by means of a description of waste avoidance practices. These include closed-cycle operation within plants, low-waste product design, and appropriate consumption behavior. This listing makes it clear that the attainment of the goal of waste avoidance depends on the understanding and fulfillment of product responsibility.

With regard to production, the Recycling Act clearly distinguishes between the plant-oriented Federal Pollution Control Act and more strongly substance-oriented waste law, in that § 9 indicates that plant-oriented requirements may be

implemented only according to the provisions of the Pollution Control Act. This holds, in particular, also for internal plant operation with substances in closed cycles. The Pollution Control Act also presumes that plants produce wastes that must be either avoided or else reclaimed in an orderly and innocuous manner.

2.3.2. Material and Thermal Reclamation

The delimitation of material and thermal reclamation is essentially based on § 4 Sect. 1 No. 1, which sets a clear priority for avoidance before any type of reclamation. Only when avoidance is not possible, in particular because of closed-cycle operation within a plant or the reduction of the quantity and pollutant level of waste, the second requirement for reclamation comes into play. A legal definition of material reclamation appears in § 4 Sect. 3; of thermal reclamation, in § 4 Sect. 4.

Material Reclamation. Three forms of material reclamation are distinguished:

1) The replacement of raw materials by recovering substances from wastes (legal definition: "secondary raw materials"). Example: manufacture of pulp from recycled paper to cut down new pulp production (conservation of forests).
2) Utilization of the material properties of wastes for the original purpose. Example: production of motor oil from waste oil.
3) Utilization of the material property of wastes for other purposes with the exception of direct energy extraction. Example: use of composted sewage sludge in agriculture.

The boundaries between modes of material reclamation are often fluid. Even an analysis of whether the principal purpose of the measure lies in the utilization of waste or the elimination of its pollutant potential (§ 4 Sect. 3 Clause 2) often can be decided only on a case-by-case basis. Abstractly, the only further prerequisite for reclamation is that the waste has been treated at all. Accordingly, reclamation is only the economically significant use of wastes for new application areas after physical, chemical, or biological treatment. The concretization of the material reclamation modes and their priority with respect to thermal reclamation, to be assessed under global ecological criteria, will have to be carried out in the framework of regulations oriented toward substances or industrial sectors.

Thermal Reclamation. According to § 4 Sect. 4, energetic reclamation includes the use of wastes as a substitute fuel. The preference for energetic reclamation over disposal means that thermal treatment of wastes in order to dispose of them, particularly of household waste, is ruled out. The distinction between energetic reclamation and thermal treatment is handled in the following way by the act: The principal purpose of the action must be recorded, that is, energy production on the one hand or volume reduction with elimination of pollutant potential on the other hand. The basis for determining the principal purpose is the individual waste, without allowance for its blending with other substances. Furthermore, the nature and extent of its impurities as well as the further wastes and emissions generated by its processing determine whether the principal purpose is oriented toward reclamation or treatment. This means that the larger and more hazardous the quantity of further wastes and emissions, the more a thermal treatment of wastes is indicated. This thermal treatment has no priority over the disposal of household waste, so that incineration of the latter is not mandated.

2.4. Legal Formulation of Recycling

Articles 5 to 9 of the Recycling Act govern the duties of the producer and owner of wastes. The fundamental duties of the consignees are addressed in § 5. These are concretized in the following standards.

Article 5 Sect. 1 concerns waste avoidance; § 5 Sects. 2 – 5 govern waste reclamation. According to § 5 Sect. 1, the duties related thereto are oriented to § 9 together with regulations issued pursuant to §§ 23 and 24. Waste avoidance is not absolutely made a legal duty in the Recycling Act, but must be implemented only in the framework of regulations yet to be issued.

The concern of § 5 Sect. 2 is reclamation in relation to disposal. Reclamation takes priority over disposal except as provided by the act.

Such provisions are found in § 5 Sects. 4 – 6. The act contains three cases in which the priority of reclamation is not applicable: nonfeasibility of fulfilling the criteria cited in Sect. 4; waste disposal as a more environmentally safe solution; research and development privilege.

According to § 5 Sect. 4, the duty of reclamation of wastes must be observed provided this is technically feasible and economically acceptable, in particular, that a market exists or can be created for a substance recovered or energy extracted. According to § 5 Sect. 5, the priority of reclamation of wastes is set aside when disposal of the wastes is the environmentally safer solution. The act establishes four criteria to be used in assessing which solution is environmentally safer: (1) the emissions to be expected, (2) the goal of conserving natural resources, (3) the energy to be consumed or produced, and (4) the enrichment of pollutants in products, wastes for reclamation, or articles obtained therefrom.

The relationship of material and energetic reclamation is governed by § 6. The environmentally safer mode of reclamation takes priority. The criteria of § 5 Sect. 4 apply. The German Federal Government can, by regulation pursuant to § 6 Sect. 1 Clause 2, state the priority of material or energetic reclamation for individual types of substances. If no such regulation exists, § 6 Sect. 2 permits energetic reclamation only if (1) the heating value of the individual waste, without blending with other substances, is at least 11 000 kJ/kg, (2) a combustion system efficiency of at least 75 % is achieved, (3) the heat evolved is itself utilized or conveyed to third parties, and (4) the further wastes generated in the course of reclamation can be placed in landfills, if possible without further treatment. Requirements on the quality of reclamation are also set forth in § 5. According to Sect. 2 Clause 2, a high-quality reclamation consistent with the nature and quality of the wastes is to be sought. The Federal Government can, under § 7, issue regulations governing the details of recycling, in particular of waste reclamation.

2.5. Disposal Standard – TA Abfall

According to § 10 Sect. 4 of the Recycling Act, waste disposal must not impair the welfare of the public. In particular, the health of persons must not be harmed; animals and plants endangered; waters and soil harmfully affected; noxious environmental impacts brought about by air or noise pollution; the interests of regional policy or land-use planning, nature conservation, and landscape conservation, as well as urban development interfered with; or the public safety and order threatened or disturbed. Articles 10 and 11, however, leave the question open as to what technical requirements are to be imposed on the nature and mode of waste disposal in individual cases for reasons of environmental protection. In § 12 Sect. 2, it is therefore provided that such details can be established in general administrative regulations by the Federal Government.

2.5.1. TA Abfall

On the basis of the standard corresponding to this provision (§ 4 Sect. 5 of the Waste Act of 1986), the first part of the Second Technical Directive on Waste (2. Technische Anleitung Abfall) was issued in two subparts [16]. It establishes a new technical framework of conditions for waste treatment, consistent throughout the Federal Republic, and, like TA Luft and TA Lärm (Technical Directives on Air and on Noise, respectively), is binding only on the executive, not the citizen. It guides the discretion of the state authorities having jurisdiction over the execution of the Waste Act and its implementing regulations. The authorities base their technical tests on the standards of TA Abfall. In particular for the approval and operation of hazardous waste disposal facilities and for the allocation of wastes to disposal paths in accordance with §§ 8 ff of the Waste and Residue Monitoring Regulation, TA Abfall contains instructions to the administration. The technical requirements of the part issued in April 1990 concern the storage, physicochemical and biological treatment and combustion of wastes subject to special monitoring. The supplement of December 1990 has to do with their aboveground and underground disposal. Wastes to which TA Abfall is applicable are conclusively enumerated in Annex C. The listing of 346 types of waste subject to special monitoring is identical with the Annex to the Waste Determination Regulation. It contains, however, additional columns for the allocation

of wastes to certain disposal paths, specifically to:

1) Chemical-physical-biological (CPB) treatment facilities
2) Household-waste incineration plants or other waste incineration plants to which the TA Abfall does not apply
3) Incineration plants for wastes subject to special monitoring (hazardous-waste incinerators)
4) Household-waste landfills or other landfills to which the TA Abfall does not apply
5) Aboveground landfills for wastes subject to special monitoring (hazardous-waste landfills)
6) Underground disposal sites in salt formations for wastes subject to special monitoring

In this way, the TA Abfall allocates wastes for the first time to certain disposal paths in order to prevent such wastes from impacting the environment or being deposited in household-waste landfills for lack of alternatives.

Number 4.4 of the TA Abfall governs the criteria under which wastes are to be allocated to disposal methods and facilities. They will have the consequence that wastes must be increasingly refused landfill disposal and must be forwarded to preliminary treatment. This leads to the situation where, for the treatment and preparation of wastes subject to special monitoring for landfill disposal, supplemental treatment capacities must be created on a large scale. Implementation of this allocation begins, according to Number 4.2, with a general ban on mixing, so that the waste composition and the pollutant level are not modified in order to evade the intended allocation.

2.5.2. TA Siedlungsabfall

The Federal Government has issued the Technical Directive on Municipal Waste (TA Siedlungsabfall) [17], which came into force on June 1, 1993. In contrast to the TA Abfall, Part 1, which applies to all wastes cited in the Waste Determination Regulation, a delimitation of the waste types to be included had to be found for the TA Siedlungsabfall. It covers the following waste categories: household waste, bulky waste, residential-type commercial wastes, garden and park wastes, market wastes, street sweepings, construction wastes, sewage sludge, fecal matter, fecal sludge, residues from wastewater-treatment plants, water-treatment sludges, and product-specific wastes, that is, wastes arising in industry, trade, or other institutions that are not municipal wastes but whose nature, pollutant content, and reaction behavior allows them to be disposed of like municipal wastes.

TA Siedlungsabfall is intended to regulate the requirements on the disposal of municipal wastes, consistent throughout the Federal Republic, such that the welfare of the public is not impaired [18]. For this reason, the technical directive contains framework conditions for the disposal of municipal wastes with allowance for disposal safety, resource conservation, relief of load on disposal facilities, and diminution of pollutant impacts on the environment. The goal is to support bodies with the duty of disposal in taking on the task of environmentally safe disposal of municipal wastes to be performed by them. The Federal Government regards a future-oriented, integrated waste management concept to be essential for handling the problem of waste. This means that an interconnected, intercoordinated system of methods and techniques for avoidance, pollutant level reduction, material reclamation, treatment of wastes not lending themselves to material reclamation, and environmentally safe disposal of pretreated wastes should be applied to the various types of municipal wastes.

The new administrative regulation established strict environmental requirements on the disposal of municipal wastes. The goal is to reduce the quantities of municipal wastes reaching the landfill. The Federal Government, in issuing TA Siedlungsabfall, pursued the goal of having the bodies with the duty of disposal largely exhaust the possibility of material reclamation and pollutant level reduction. To this end, the criteria for the allocation of waste streams to disposal processes and requirements on material reclamation (including composting) and pollutant level reduction are standardized. An essential criterion for reducing the amount of waste to be landfilled is reclamation. In order to secure this, TA Siedlungsabfall begins with the principle of segregation. Thus pollutants and valuable substances are always to be collected separately in order to permit utilization of the valu-

able substances or to facilitate the handling of reclaimable residual wastes.

An important part of the technical directive concerns future requirements on environmentally safe landfill disposal of residual wastes that cannot be avoided or reclaimed. Even if all possibilities of meaningful reclamation are exhausted, there will always be municipal wastes that must be permanently disposed of in landfills. To this end, the technical directive sets up requirements, first, on the quality of wastes for landfilling and, second, on the sealing systems necessary in future landfills. For this, the technical directive provides for the pretreatment of wastes to be disposed of in landfills, in particular by incineration. Furthermore, it creates requirements on environmentally safe disposal of residual wastes that cannot be avoided and reclaimed by means of a variety of landfill types.

2.6. Hierarchy of Responsibility

According to § 11 Sect. 1 of the Recycling Act, the producer or owner of wastes has the duty to dispose of them. Anyone who produces or owns wastes, including private persons, himself has the duty of disposal. This statement is negated for certain cases in §§ 13 to 18, but nothing in the fundamental duty is changed. Exceptions to the duty, existing for everyone, to dispose of wastes oneself appear in § 13. The first exception is for wastes from private households. If private households are not in a position to dispose of their wastes or if they have no intention of private disposal, then under § 13 Sect. 1 Clause 1 they must yield these wastes to corporate bodies obligated under state law to dispose of them. This also holds for producers and owners of wastes for disposal from other areas of origin if they do not dispose of these wastes in their own facilities or if overweighing public interests require such yielding. The exception stated in Clause 2 holds for any conceivable waste; the duty to yield must be concretized by a municipal ordinance. According to § 13 Sect. 2, the duty to yield wastes under Sect. 1 does not exist with respect to public-law disposal utilities when the duties of reclamation and disposal have been transferred to third parties or private disposal utilities. The duty to yield wastes does, however, exist under § 13 Sect. 2 Clause 3 for wastes that (1) are subject to a take-back or give-back duty based on a regulation pursuant to § 24, unless the public-law disposal utilities cooperate in the take-back on the basis of a provision pursuant to § 24 Sect. 2 Number 4; that (2) are delivered via public collection to an orderly and innocuous reclamation; that (3) are delivered via commercial collection to an orderly and innocuous reclamation, provided this is demonstrated to the public-law disposal utilities and not overweighing public interests stand against this.

According to § 13 Sect. 4, the German Federal States can (as some already do) decree duties to deliver and yield wastes subject to monitoring.

Corresponding to the duty to yield wastes is the duty of public-law disposal utilities to dispose as set forth in § 15. The duty to reclaim according to the standards of § 5 Sect. 4 takes priority over the duty to dispose.

Under § 16, the public-law disposal utility can transfer its legal duties in whole or in part to a third party, with the consequence that the public-law disposal utility involved is released from all duties. This is, however, possible only under the conditions set forth in detail in the statute.

2.7. Approval of Waste Disposal Facilities

All waste disposal facilities, whether internal to a company or of a public-law nature, are subject to inspection by the state agency having jurisdiction; this provision refers to landfills, refuse incineration and composting and other plants, as well as equipment in which wastes are treated, stored, or transferred.

For both the erection and the operation of a fixed waste disposal facility, § 31 Sect. 1 provides for approval of the plan by the agency having jurisdiction. The sense and purpose of this rule is to afford the agency the possibility of verifying whether the conditions of an environmentally safe waste disposal facility are satisfied. The approval procedure, which is set forth in the Administrative Procedures Act (Verwaltungsverfahrensgesetz, VwVfG), is divided into three phases: creation of the plan by the proposer of the project; the hearing and discussion procedure opened on submission of the plant at the hearing (§ 79 VwVfG), and the procedure involving the establishment of the plan (§ 74

VwVfG). In the best case it offers an assurance that the many interests concerned will be comprehensively examined, weighed, and balanced.

In place of the plan approval procedure, on application or on agency initiative, pursuant to § 31 Sect. 3 of the Recycling Act, an approval procedure can be carried out if the project concerns the erection or operation of an insignificant waste disposal facility, if objections are not anticipated, or if substantial changes in a facility or corporation are at issue. As a result of this possibility of plan approval, the procedure is supposed to be simplified and speeded up. It is, however, of little importance with respect to the disposal of wastes subject to special monitoring, since as a rule a hazardous waste incineration plant or landfill will not be an insignificant facility. Because of the lack of public acceptance, objections can be expected as a matter of course. Thus § 31 Sect. 3 will come into play, at most, with regard to the approval of substantial modifications in an existing facility or its operation.

Even before the establishment of the plan or before granting of final approval, performance can be started in advance under the conditions cited in § 33.

The approving agency is required to approve only those facilities that satisfy the requirements of TA Abfall; that is, they must fulfill the criteria for the allocation of wastes to disposal methods and to disposal facilities, as well as the requirements imposed on the facilities. Annex A of TA Abfall contains details on approval applications and application documents.

Unapproved facilities must either be abandoned and removed or legalized after the fact. In either case, operation of such facilities is an offense under § 327 Sect. 2 No. 2 of the German Criminal Code (Strafgesetzbuch).

As a rule, the approval of a waste disposal facility takes place by plan approval procedures. No other official decisions are required aside from plan approval; in particular, no publiclaw approvals, grants, permissions, consents, endorsements or other plan approvals are required. A plan approval decision governs all public-law relationships between the proposer of the project and the parties concerned. The plan approval decision must include in its finding all considerations of substantial weight. It must leave no open questions [19].

In the framework of a plan approval procedure, the environmental safety of the facility must always be tested pursuant to § 31 Sect. 2 Clause 2. This environmental safety test is a non-self-contained procedural component of the plan approval (§ 2 Sect. 1 of the Environmental Safety Test Act, UVPG). This means that the environmental safety test takes place within the plan approval procedure pursuant to waste law, i.e., there is no separate environmental safety test procedure and no special environmental safety test report. Environmental impacts in the sense of the Environmental Safety Test Act are changes in human health and in the physical, chemical, or biological quality of individual constituents of the environment or the environment as a whole. The testing of these environmental impacts is prescribed as to form, and must follow the procedural steps required by §§ 5 to 12 of the UVPG.

A complaint against a plan approval decision – an administrative action in the sense of § 35 Sect. 1 of the Administrative Procedures Act – can be lodged without prior objection, § 79 VwVfG, in conjunction with § 69 of the Administrative Courts Regulation (VwGO); that is, no prior procedure is required. In order to further speed up the action of law, the "Oberverwaltungsgericht" (a high administrative court) decides in the first instance, pursuant to § 48 Sect. 1 No. 5 VwGO, if there is opposition to the erection, operation, or a substantial modification of a fixed waste disposal facility in which extra wastes are stored or transferred or in which more than 100 000 t/a of wastes are incinerated or thermally degraded.

2.8. Monitoring of Waste Disposal

The numerous provisions of waste legislation can exert their environmentally protective actions only if there is an assurance that their observance is monitored and secured by effective control mechanisms.

2.8.1. Monitoring

According to § 40 Sect. 1 of the Waste Act, all phases of waste disposal are subject to monitoring by the agency having jurisdiction. This means that not only the owners of wastes, the

proprietors of waste disposal facilities, and natural persons and corporate bodies of civil law concerned with the collection and transportation of wastes are subject to monitoring, but also the public-law disposal utilities (pursuant to § 13 of the Recycling Act) and third parties contracted by them (§ 16). Articles 42 and 43 govern the various accountabilities of the owners of wastes. According to § 43 of the Waste Act, producers, collectors, or transporters and disposers of wastes subject to special monitoring are directly obligated by force of statute

1) To keep a book of accounts
2) To present certificates
3) To demonstrate to the agency having jurisdiction that the legal conditions for special accountability are satisfied on their part

How the accounts of the whereabouts of wastes are to be kept pursuant to § 43 of the Waste Act is governed in detail in the Waste and Residue Monitoring Regulation [20], which superseded the Waste Accountability Regulation (Abfallnachweis-Verordnung). According to §§ 8 and 12, an owner of wastes or residues must declare the permissibility of disposal before performing the disposal. In this way, the regulation creates an obligation of prior demonstration, as is already practiced by many landfill operators.

The disposal permit according to Annex 3 is to be used when the disposal of wastes requiring a permit is contemplated, i.e., for extra wastes and other wastes when accountability has been instituted by the agency having jurisdiction over wastes. It is valid for a maximum of five years.

The collection and disposal permit, which can simplify the procedure under the conditions of § 10, comes into play in the collection of small quantities of wastes containing pollutants.

The simplified disposal permit of § 12 is to be used for refuse not subject to accountability.

For household waste and other wastes that can be disposed of with wastes produced in households, no disposal permit is required, even for household waste containing pollutants.

According to § 42 Sect. 1 of the Recycling Act, the agency having jurisdiction can by administrative action obligate the owners of such wastes that cannot be disposed of together with wastes produced in households, or can be so disposed of only under special precautions, to

1) Present evidence of the nature, quantity, and disposal of wastes (general accountability)
2) Keep an accounts book
3) Retain and safeguard certificates and accounts and submit certificates for examination (special accountability)

Such an arrangement is within the discretion of the regulatory agency. It can therefore institute the permit only for certain wastes or solely with respect to a means of accountability.

2.8.2. Transportation Approval

In order to ensure orderly waste disposal, it is further necessary that the authorities be able to examine the specialist, technical, and personal conditions of those persons and companies that collect and transport wastes. Here § 49 of the Recycling Act offers a legal foundation that provides a transportation approval for companies that commercially collect wastes for disposal. Unsuitable persons or companies can thus be prevented from handling wastes in dangerous or incorrect ways.

Commercial collection and transportation takes place when there is a self-contained activity aimed at earning a profit and created for a certain span of time. It takes place in the framework of commercial enterprises when it is performed with no profit motive for internal purposes of a commercial company or a public enterprise producing goods for consumption. The latter, practically, is the case only when the company brings its own wastes to the waste disposal facility, so that the owner of the wastes is simultaneously also the transporter of the wastes.

The form of the approval procedure is governed by §§ 4 – 7. In order to grant a transportation approval, the authorities test the reliability of the applicant and, for this purpose, request the documents listed in § 4 Sects. 1 and 2. For this reason, the approval is not transferrable (§ 6). Reliability presupposes that the transporter employs personnel subject to his instructions. Further, the capability of the waste transporter must be verified (§ 4 Sect. 1). The transporter must demonstrate adequate liability insurance, with a limit of at least € 2.6×10^6. Transportation approval may be denied on the grounds of the general welfare if the application is for roundabout transportation with an excessively high risk.

If all the conditions are met, in particular if there is no anxiety as to impairment of the public welfare, the applicant has a claim to issuance of the approval pursuant to § 49 Sect. 1 Clause 1 of the Recycling Act.

2.9. Plant Officer for Waste

Official monitoring of waste disposal is supplemented by internal monitoring. For facilities in which wastes subject to special monitoring are produced regularly, and also for fixed waste disposal facilities, a plant officer for waste must be designated. Which plants are affected by this provision is set forth in detail in § 54 Sect. 1 of the Recycling Act and § 1 of the Regulation on the Plant Officer for Waste (Verordnung über den Betriebsbeauftragten für Abfall, AbfBetrbV).

Essentially, a plant employee must be designated as the plant officer for waste. This person's knowledge of the operation should help reveal opportunities for waste avoidance and waste reclamation. A person from outside the plant may, however, also be appointed plant officer. In this case, prior agreement of the agency having authority is required under § 4 of the AbfBetrbV.

The tasks and authority of the plant officer for waste are set forth in § 55 of the Recycling Act. This officer must observe, examine, and collaborate in the actions identified in § 55 Sect. 1 No. 1 to 5 of the Waste Act, must submit reports, must issue a position on certain investment decisions, and must advise, report, and cooperate. Within the plant, he must aid in the performance of duties under waste law, for example in waste avoidance and reclamation, and in particular must advise the plant owner in these matters. In his annual report, the plant officer must report in what monitoring actions and inspections have been performed and whether any reports of plant upsets have been submitted.

2.10. Waste Management Concepts and Balances

2.10.1. Waste Management Concepts

According to § 19 of the Recycling Act, producers generating in all 2000 kg/a of wastes subject to special monitoring, or more than 2000 t/a of wastes subject to monitoring per waste code, must create a waste management concept relating to the avoidance, reclamation, and disposal of the wastes produced. The producer's waste management concept functions, on the one hand, as an internal planning tool and, on the other hand, as a basis for official waste management planning. To this end, it must be presented for evaluation if requested by the agency, having jurisdiction. The content of a waste management concept is governed in detail by § 19 Sect. 1 Clause 3. According to Sect. 2, the waste management plan data pursuant to § 29 must be taken into consideration when this plan is prepared.

2.10.2. Waste Management Balances

According to § 20 Sect. 1, those having duties in the sense of § 19 Sect. 1 must prepare annually (starting on April 1, 1998) a balance for the prior year, showing the nature, quantity, and whereabouts of wastes subject to special monitoring and wastes subject to monitoring that have been reclaimed or disposed of. According to § 20 Sect. 2, those with the duty of preparing a waste balance have a right to information relative to owners of wastes from commercial or other economic enterprises or public institutions insofar as these have yielded wastes to those having the duty.

2.11. Remediation of Hazardous Waste Sites

In order to avert hazards to human health and groundwater quality, hazardous waste sites must be remediated. The legal conditions for such remediation have not yet been formulated in a self-contained way applicable throughout the Federal Republic. Rules for the identification, testing, hazard evaluation, and remediation of hazardous waste sites as well as financing are found in the bodies of law relating to wastes, water, mining, police powers, and order.

2.11.1. Duty to Remediate

Since the Waste Disposal Act (Abfallbeseitigungsgesetz) of 1972 took effect, the creation

of new hazardous waste sites with unforeseeable financial consequences for the public has been barred. According to § 36 of the Recycling Act, the waste authorities, under § 36 Sect. 2 of the Recycling Act in the case of the closure of a waste disposal facility, and under § 36 Sect. 3 of the Waste Act in the case of the closure of commercial facilities in which wastes subject to special monitoring are produced, can require recultivation as well as protective measures if this is necessary to guard against impairment of the public welfare. The operator of the facility and the proprietor of the land have the duty of remediation.

For conditions dating from the time from March 1, 1960 [when the Water Resources Management Act (Wasserhaushaltsgesetz) took effect] until June 11, 1992, the Water Resources Management Act can be applicable if the storage or landfill disposal of substances fulfills a disallowed water use (§ 3 Sect. 1 No. 4 or 5, § 3 Sect. 2 No. 2, § 22 Sect. 2, § 26 Sects. 1 and 2, § 34 Sect. 2, all of the Water Resources Management Act). Substances may be stored near a body of water only in such fashion that there need be no concern over harmful contamination of the water or any other detrimental change in its properties or in the discharge. On the basis of the framework provisions of the Water Resources Management Act and the state water legislation supplementing it, the authorities can order remediation [21]. Liability for costs is governed by state legislation.

For facilities closed or contaminations caused before March 1, 1960, only the state water legislation or its predecessor legislation applies insofar as it contains provisions extending beyond the general police power. Because of the constitutional ban on a genuine retroactive character of statutes, there is no recultivation and remediation duty under German Federal Law extending back beyond March 1, 1960.

Subsidiarily, the provisions of general police power are cited for averting hazards from hazardous waste sites. The police power is, however, oriented toward the maintenance of present safety and order; it permits necessary actions to limit damage but, as a rule, not remediation actions. A hazard originating from a hazardous waste site can be responded to under police powers by recourse to the polluter or also to the proprietor or possessor of actual power.

2.11.2. Other Duties

For all waste disposal facilities that were operated or erected before June 11, 1972 and are still in service, the agency with jurisdiction can, pursuant to § 35 of the Waste Act, issue subsequent orders, set deadlines, conditions, and specifications, and even order the cessation of operation. For facilities approved after June 11, 1972, changes in operation can be ordered only pursuant to § 32 Sect. 4 Clause 2 of the Recycling Act.

Under § 40 Sect. 1 Clause 2 of the Recycling Act, monitoring under waste law can also be extended to closed waste disposal facilities and to plots of land on which wastes were produced, treated, stored, or transferred before June 11, 1972, provided this is necessary to protect the public welfare.

If dwellings have been built on hazardous waste sites, the agency with jurisdiction can order their demolition if the hazardous waste sites present health risks to the residents.

2.11.3. Financing of Remediation of Hazardous Waste Sites

The remediation of hazardous waste sites entails high costs. A reliable total cost estimate does not exist, but a figure spoken of is up to € 35.8×10^9. Various financing models are under discussion and have already been introduced in some German Federal States.

The License Model of North Rhine-Westphalia. The North Rhine-Westphalia State Waste Act, in its fourth part, governs the issuance of licenses for the treatment or transfer of wastes that are excluded under § 15 Sect. 3 of the Recycling Act (§ 10 Sect. 1 of the North Rhine-Westphalia State Waste Act). Licenses are granted by the State Water and Waste Office. According to § 11 Sect. 1 of the North Rhine-Westphalia State Waste Act, a fee is charged for working the license; by § 15 Sect. 1 of the North Rhine-Westphalia State Waste Act these fees are dedicated to hazardous waste site remediation and further tasks of the "Entsorgungsverband" or disposal association. This model is intended

to solve problems of hazardous waste disposal and hazardous waste site remediation at the same time. The coordination of both areas by means of the dedicated fees and the mandatory membership of private disposal companies in the North Rhine-Westphalia Disposal Association (§ 5 of the Disposal Association Act) is justified with numerous parallels that can lead to a transfer of technology and know-how.

The Cooperation Model. In Rhineland-Palatinate and Hesse, the "cooperation" model is in effect. The state and local governments and businesses cooperate in administering hazardous waste site remediation by establishing a company to dispose of hazardous wastes with remediation functions.

2.12. Criminal Offenses and Infringements of Regulations

Unlawful disposal of waste is punishable, under numerous provisions of German Federal and State Law, by monetary penalties and fines and, in some cases, by criminal fines or imprisonment.

German Federal Law provides criminal penalties for offenses as follows:

– § 326 of the Criminal Code (waste disposal endangering the environment)
– § 327 Sect. 2 No. 2 and Sect. 3 No. 2 of the Criminal Code (unapproved operation of a waste disposal facility)
– § 330 (severe endangerment of the environment)
– § 13 in conjunction with § 7 Sect. 3 Clause 2 of the Radiation Protection Precautions Act (violation of dose and contamination values)

Fines are assessed for the following offenses:

– § 61 of the Recycling Act (unlawful waste disposal)
– § 7 of the AbfKlärV (unlawful handling of sewage sludge)
– § 9 of the Waste Accountability Regulation (incorrect bookkeeping)
– § 5 of the PfandV (failure to levy deposit on plastic bottles)
– § 12 of the Packaging Regulation (packagings harmful to the environment)
– § 10 of the Waste Oil Regulation (unlawful handling of waste oil)
– § 19 Sect. 1 No. 2 of the Dead Animal Disposal Act (unlawful disposal of dead animals or animal body parts other than in dead animal disposal facilities)
– § 46 Sect. 1 No. 4 of the Atomic Energy Act (unlawful disposal of radioactive substances)
– § 41 Sect. 1 No. 9 in conjunction with § 26 Sect. 1 of the Water Resources Management Act (release of solids into a body of water for the purpose of disposing of them)

What is understood by "waste" in criminal law is based on the waste concept of the Waste Act, but is oriented to different standards than in waste law. What is at issue is not the intent of the owner of movable property to reclaim it, but its objective use value. If, for example, an item of property is at present objectively without use value because of its contamination, but its condition is such as to threaten the environment, then it is waste in the sense of § 326 of the Criminal Code. This holds even if the owner wishes to reuse or reclaim the substance or its constituents after disposal [22]. The waste concept of § 326 of the Criminal Code also differs from that of waste law in that the criminal law does not adopt the application restrictions provided in § 1 Sect. 2 of the Waste Act for substances whose disposal is governed by special provisions. On the other hand, the criminal concept of waste is not enlarged by the fictions of §§ 5 Sect. 2, 5a, and 15 of the Waste Act.

2.13. Civil Liability

2.13.1. Product Responsibility

According to § 22 Sect. 1 of the Recycling Act, product responsibility for fulfilling the goals of recycling is borne by the one that develops, manufactures, finishes, and processes or sells products. For the fulfillment of product responsibility, products must be designed so that the production of wastes is decreased as much as possible in their manufacture and use, and the environmentally safe reclamation and disposal of wastes produced after their use is ensured. Product responsibility is defined more closely

in § 22 Sect. 2 of the Recycling Act. Who bears product responsibility is not based on the statute; instead, the German Federal Government determines, by regulation pursuant to §§ 23 and 24 of the Recycling Act, what parties having duties are to fulfill the product responsibility according to § 22 Sects. 1 and 2 of the Recycling Act. The Federal Government further established by regulation for what products and in what fashion and manner product responsibility is to be assumed.

2.13.2. Damage Claims

The Recycling and Waste Act contains no provisions as to the civil liability for waste-related harm that may be done on the path from waste production to final waste disposal. Claims for compensation of damages are furthermore governed by the general rules.

Noncontractual liability for damages caused by wastes is essentially determined according to the provisions of §§ 823 to 853 of the German Civil Code. Anyone harming the life, the body, the health, the freedom, the property, or any other right of another by malice or negligence is obligated to compensate the other for the damage. The damage must be caused illegally and culpably. The jurisprudence here has developed on the basis of a producer liability, which extends so far that even wastes in the field of industrial wastes are included in the liability and a responsibility for the state/safety of something ("Verkehrssicherheitspflicht") has been developed and facilitations of the burden of proof ("Beweiserleichterungen") have been created. According to § 823 Sect. 2 of the Civil Code, furthermore, violation of a statute that seeks to protect another creates an obligation of compensation for damages. Article 22 of the Recycling Act in conjunction with regulations still to be issued pursuant to §§ 23 and 24 of the Recycling Act is such a protective statute. Claims for compensation of damages can also arise from violations of contractual duties. The basis of the claim is then the institute of positive infringement of claim [23] as developed by jurisprudence. The Product Liability Act [24] was adopted to protect the consumer against harm to his health and his property by a defective product. This statute justifies a liability independent of culpability, which can also come into the picture when a defective product causes a harm upon its disposal. The Environmental Liability Act [25] introduces a liability of endangerment, independent of culpability, for the operators of one of the facilities enumerated in the Annex to the act. In this way, the safety of these facilities is supposed to be enhanced. If the environmental impact of a facility kills a person, harms another, or damages property, the proprietor of the facility must make recompense for damages.

3. Organization of Hazardous-Waste Disposal

At present the catalog of hazardous wastes includes 331 well-defined substances; presumably the number will increase as more and more substances are recognized as meriting special attention.

The quantity of hazardous wastes is decreasing because waste-prevention and waste-reduction efforts in industry and business, such as closed process loops for acids and scrubbing liquors, are succeeding; waste reclamation is being increasingly practiced in waste-generating plants; and because recycling processes have been improved.

With regard to quality, too, the generation of hazardous wastes will continue to change. Because pollutant concentrations in hazardous wastes are increasing, the quality of treatment has to meet more stringent requirements. Wastes for deposition must be subjected to increasingly differentiated pretreatment.

As a consequence, more and more effort and expense are going into the organizational, technical, and cost aspects of hazardous-waste treatment. Logistics as well as treatment and reclamation management must be flexible so as to adapt to waste quality and quantity, regional variations in occurrence, and technical developments. Requirements on the organization of hazardous-waste management must be viewed against this background.

The German hazardous-waste disposal market is split in two. The large chemical companies have their own high-quality disposal facilities, which, with a few exceptions, are not available for waste disposal by other companies. These industrial and commercial businesses transfer

Table 7. Hazardous-waste disposal companies in Germany [26]

Land	Address		Share capital, €	Ownership

their especially hazardous wastes to third parties. Often these markets are regulated, and in each German Land the market is dominated by one disposal company. Information on the situations in the Länder can be found in Tables 8 and 7.

In six of the Länder, hazardous-waste disposal is wholly or mainly in public hands because the company is majority publicly owned. In four Länder, state-owned companies handle part of the hazardous waste, and in six this waste is disposed of by private companies (Table 8).

The state companies have the following primary tasks:

1) To ensure the disposal of hazardous wastes by creating and committing adequate disposal capacities
2) To guarantee the proper disposal of hazardous wastes through
   a) Monitoring (waybill system)
   b) Directing wastes to suitable facilities
   c) Maintaining records of waste quantities(statistical recording)

Along with these functions, some states have developed corporate structures and gone into competition with private companies. The associations of private waste-disposal contractors are critical of the situation in those states where such companies have taken over part or all of hazardous-waste disposal, citing:

1) Excess capacity of facilities
2) Lack of flexibility to adapt to changes in waste quantity
3) Price autonomy due to self-created monopoly structure
4) Rising costs, for example due to increased administrative fees, hazardous-waste levies, license fees, and so forth
5) Assumption of consulting functions
6) Elimination of competition in hazardous-waste disposal
7) Harm to competitiveness of industrial regions

8) Impairment of Germany as an industrial location
9) Covert supplemental financing of Land economies

Private disposal contractors also claim superiority over state-owned companies with regard to efficiency. For example, state-owned companies achieve a recycling rate of only 20 %, while private companies had a rate of over 30 % in 1994.

In particular, it seems questionable when state-owned companies mingle governmental functions, such as taxation, supervision, and monitoring, with commercial interests. They control markets and override market principles.

A change also appears called for in the preference for disposal in the same Land. Because enhanced environmental awareness has reduced waste volumes, environmental protection has become integrated into corporations, production processes generating less waste have been adopted, and feedstocks with lower pollutant concentrations have come into use, virtually all reclamation, treatment, and disposal facilities have developed excess capacity. If the existing facilities can accept waste from anywhere in Germany, they will be better utilized, fewer new facilities will have to be built (especially in the former Democratic Republic), and costs for hazardous-waste disposal will decline.

European facilities must also be included in the disposal scheme to the extent that these facilities are as good as or better than domestic facilities and comply with the provisions of the 17th German Federal Pollution Control Act.

It is also important that waste-disposal companies have their waste-treatment facilities certified, because this quality attribute satisfies a security need on the part of their customers.

4. Life-Cycle Assessment

4.1. Introduction

Human activity in the form of production, consumption, and disposal imposes a variety of burdens on and, in some cases, irreversible damage to the environment. The purpose of "sustainable development" is to minimize these environmental burdens. The diverse interrelations between material and energy streams and processing operations makes it uncertain whether individual measures taken together lead to a lessening of such burdens. Accordingly, a method is needed by which environmental burdens due to systems, as well as their mitigation, can be quantified. This method is known as life-cycle assessment (LCA) [27], [28].

Definition and Goal. Life-cycle assessment is a method by which environmental burdens caused by a material or immaterial object of investigation, including potential effects, can be determined. Objects of investigation are, firstly, products and services; companies, facilities, disposal routes, and so forth can also be treated in this way. The LCA consists of the following phases: goal definition and scoping, inventory analysis, impact assessment, and interpretation. In the goal definition phase, reference quantities, system boundaries, and level of detail are set for the assessment as a whole. The inventory analysis phase includes material and energy streams treated as inputs and outputs over the entire life cycle of the products, including the production and preparation of raw materials, production and finishing, distribution, transportation, energy production, consumption and wear and tear, and disposal (including recycling). In the framework of the impact assessment phase, the first two subphases together – classification and characterization – entail a determination of potential environmental impacts (greenhouse effect, ozone degradation, etc.) for each item in the inventory analysis. In the last subphase of impact assessment, interpretation, potential impacts in the various environmental categories are collectively evaluated. The results of a life-cycle assessment are used in selecting the ecologically most favorable variants, environmental optimization of existing systems, and development of new systems (products, services, etc.; see Section 4.2). For this reason, the LCA must be clear, reproducible, and mathematically consistent, and it must be prepared in time periods in accord with knowledge interests [27–31].

Status of the Life-Cycle-Assessment Method. The LCA method is still under development. Inventory analysis has been developed furthest, while interpretation is least advanced.

The technique of classification and characterization occupies an intermediate position. While both inventory analysis and the classification and characterization subphases are based on scientific rules, this is only partly possible in the interpretation subphase, which involves environmental objectives among other factors [29].

In spite of the partly subjective valuation technique and other fuzzy areas, LCA is a very good decision aid in industry and commerce, since the most complex relationships are systematically reduced to a few data sets. LCA is already a useful instrument for objectivizing the environmental burdens that actually result from an object of investigation. Life-cycle assessments must be performed under recognized rules, such as those created by the DIN body NAGUS (Standards Committee on Principles of Environmental Protection) and ISO:

ISO 14 040: Environmental management – life-cycle assessment – principles and guidelines
ISO 14 041: Environmental management – life cycle assessment – life-cycle-inventory analysis
ISO 14 042: Environmental management – life cycle assessment – life-cycle-impact assessment
ISO 14 043: Environmental management – life-cycle assessment – life-cycle-improvement assessment

4.2. Scope and Limits of Life-Cycle Assessments

Life-cycle assessments consider only environmental aspects; they accordingly form just one element needed for decision-making. Technical and safety aspects are taken into account in goal definition; fulfillment of these criteria is essential for the creation of an LCA (Fig. 6). The environmental aspects are the object of the LCA; in contrast, economic and social aspects are additive, built up on the results of the LCA, rather than integral. Product-line analyses have not only environmental but also economic and social aspects as integral components, and this is where they differ from the life-cycle assessment [33].

With the help of the LCA, the environmental relevance of objects of investigation (such as products and services) can be determined in a clear and reproducible way. This accordingly is the basis for ecological optimization; the selection of ecologically "better" alternative products, substances, processes, and designs; and the environmental design and development of products [27], [28], [31].

Table 9 presents applications of LCA as they relate to products. The cases of one and more than one product, and of existing and newly developed products are distinguished. The actions listed serve to minimize the use-related environmental burdens, determined by means of the LCA. For one existing product, life-cycle assessment is employed to optimize environmental relevance over the life cycle by substitution of substances, energies, and processes. For one new product, environmentally compatible development involves the selection of suitable substances, processes, and design. In the case of several existing products, the product having the lowest environmental burden is identified by means of LCA. Any life-cycle assessment is a comparison between objects of investigation, and the same holds for optimization of a product with substance, energy, and/or process alternatives.

Table 9. Scope of application of LCA to products [34]

Product(s)	Existing	New
One	optimization	development optimization
Several (same goal function)	selection optimization	development optimization selection

In addition, the LCA technique can be used to determine the following [27], [28], [31], [35], [36]:

1) The ecologically optimal disposal route for used products and wastes
2) The ecological breakeven point for recycling and other environmental protection practices
3) Weak points in the life cycle (product line) of the object of investigation
4) Priorities of necessary actions

The LCA method is applicable to companies and plants as well as products and services [34], [37]. For each, the method is used to find a local minimum of environmental burdens. These minima, because they do not take account of the full life cycle, do not necessarily lead to a global minimum of environmental burden due to the product.

Figure 6. Aspects and elements to be considered in decision-making

The use of LCA has the following limitations [38]:

1) Environmental burdens due to an object of investigation can be determined only relatively, not absolutely, because the true impacts on the environment cannot be determined
2) No universally valid inferences can be made about the environmental compatibility of materials, auxiliaries, and media, since neither the intended use nor the anti-cipated benefit is known. Only the environmental burden up to the manufacture of the substance can be determined as an "ecological mortgage" [34]
3) Universal statements about disposal routes cannot be derived because the reference values for the used product or waste must be known

A life-cycle assessment does not yield unequivocal results (yes/no, black/white, good/bad, . . .) and therefore cannot dictate decisions, merely aid in making them.

An environmentally oriented decision must not be based solely on the result of the LCA, but must also consider the way in which the result was reached; that is, the methodology and the data used are both crucial.

4.3. Method of Product Life-Cycle Assessment

The technique of product LCA can essentially be extended to the other objects of investigation mentioned in the preceding sections. The LCA must be methodologically correct, internally consistent, clear, and reproducible, and it must be generated in the time intervals corresponding to the knowledge interests. Furthermore, it must be done in such a way that the relative environmental relevances of several products, or of one product for which alternatives (substances, energy, processes) are being evaluated, can be determined. The LCA must be in accord with the goal definition.

4.3.1. Goal Definition and Scope

4.3.1.1. Knowledge Interest and System Description

It should be stated at the outset why the LCA is being prepared, for what purpose, and by whom the results and the inferences are to be used [28]. An important question is whether the LCA is internal or public. In an internal life-cycle assessment, it may be appropriate to omit the interpretation step. The internal versus public definition

also governs what kind of critical review (Section 4.4) is to be performed and what personnel will be involved. The level of detail of the LCA must also be identified. The simplest LCA, carried out at the lowest cost, is "screening" in contrast to a "complete" LCA with its high degree of detail.

The level of detail is implied by the system description in the goal definition. The description of the product system and the definition of system boundaries of the LCA must be distinguished. The system to be investigated depends on the concrete knowledge interest. The product itself, the requirements it must meet, the conditions of its use, and other constraints must be explicitly stated. This can be done in the form of a specification. The assessment space is the geographic system boundary of the LCA. It is a delimitable space whose state can be described together with the factors influencing it. The assessment interval is the time for which the assessment is performed. It should be as close as possible to the interval in which the study is carried out; for reasons of symmetry, all data used must originate in the same time interval. The fourth system boundary of the LCA is a methodological constituent of the LCA. The assessment boundaries define the part of the product line that is to be examined and separate it from the surroundings. The assessment boundaries are determined by cutoff criteria, which in turn depend on the level of detail specified in the goal definition and may be stated in terms of a percentage. If the substance or energy in question, relative to the functional unit, falls below a specified percentage, the process chain leading to the creation of this substance or energy is no longer considered as originating in the object of investigation. The procedure for determining the assessment boundaries is iterative and can only be carried out while the inventory analysis is being performed [28], [31].

It must be stated whether the life-cycle assessment is to be carried out for a product line with specific sites taken into account ("specific" LCA) or is to be a "general" LCA based on average values or literature data. In the case of a concrete product line, the sites of production, consumption, and disposal throughout the product life cycle must be identified. The results of both types of LCA and their potential utilities differ depending on these decisions. Mixed forms are also possible, provided data symmetry is guaranteed [39]. With regard to the knowledge interest, the goal definition must also include data-quality targets (accuracy, depth of detail, completeness, consistency, congruency, symmetry, and representativeness) [40].

It must be determined whether the LCA is to be used as a static model for one-time comparison or is to form the basis for optimization and thus has to be used in calculating alternatives and scenarios and in performing sensitivity analyses. For static LCAs, the "black box" method for process assessment is adequate; in this technique, the dependences of the process output on the input are not considered. For nonstatic LCAs, on the other hand, process modeling using these dependences (Section 4.3.2.4.2) is essential [41].

4.3.1.2. Functional Unit

The object of investigation is the computational reference quantity of the product line and represents its primary benefit. All environmental burdens, impact potentials, and additional benefits are referred to the object of investigation, i.e., to the product in the case of a product LCA. Products (finished products) can be compared only if they meet identical needs and satisfy identical requirements (profile of requirements, specification). The functional unit [27], [28] goes beyond the object of investigation per se and, for the sake of comparability between product lines, considers the total benefit furnished by the system (product line) under examination, i.e., both primary and secondary (additional) benefits. The functional unit includes the product lifetime (service life, frequency of use, etc.) and, along with the object of investigation, includes the equality of benefits [42], i.e., the equality of all products created by the systems with respect to quality and quantity (Section 4.3.2.5.4).

4.3.2. Inventory Analysis

Once the goal definition (Section 4.3.1) has been completed and it has been verified that the product as well as the alternatives under consideration fulfill the functional (technical) aspects and

safety requirements according to the specification, the inventory analysis can be undertaken [31].

4.3.2.1. Components of the Product Line

In the context of life-cycle assessment, a process forms the smallest assessable element of an inventory analysis whose inputs and outputs can be identified [41]. The goal of production processes is the process product, while the goal of disposal processes is either the treatment and storage of the waste generated (disposal processes) or the reclamation of used products and wastes (recycling processes). The process goal is the process reference quantity. The product (object of investigation) and the functional unit (Section 4.3.1.2) must be distinguished from the process reference quantity. The process being assessed is broken down into production of raw materials and energy; transportation; production; consumption; and disposal, including recycling. Processes can be linked into process chains, extending up to complete product lines (Fig. 7). The product line is the model of the complex linkage of all processes via the material and energy streams for a finished product within the assessment boundaries, from raw materials extraction through the product to the reincorporation of substances in the environment. This is the model of the product life cycle. Process chains are processes directly linked together through the material stream, often within corporate boundaries, which thus represent parts of the product line. A module consists of a process or process chains that can, by virtue of their unambiguous description and well-defined interfaces, be used for a variety of LCAs [31].

4.3.2.2. Development of the Product Line

The development of the product line has the purpose of identifying all substances, energies, and processes (and process sequences) directly or indirectly involved in the manufacturing, consumption, and disposal of the product. The procedure is as follows [31]:

1) Identify the substances composing the product or that are to compose a new product.
2) Set up the basic structure (main process flow) for these substances, starting from the finished product and going up the material stream back to extraction from the Earth's crust or the biosphere.
3) Prepare the basic structure, starting from the finished product and going in the material stream direction through product use, recycling or waste processing, all the way to landfill disposal of wastes.
4) Determine the input and output substances and forms of energy for each process included in the basic structure.
5) Work out the process chains for each input and output substance and each form of energy identified in the preceding step. The result is the first-order side structure (side process flow).
6) Using the first- and higher-order side structures, proceed as in the fourth step to go from basic structure to the next order of side structure.

Because the assessment boundaries are not yet determined, the development of the product line is broken off after the first-order (sometimes the second-order) side structure has been generated, to limit the amount of work involved. The final development of the product line within the assessment boundaries can be carried out only when data acquisition is complete and the methodological cutoff criteria have been applied.

One of the prerequisites for comparing two or more products having the same purpose is the use of the same cutoff criteria for all products included (on grounds of symmetry) [39].

4.3.2.3. Data Acquisition

Data may be measured, calculated, or estimated; averages or ranges can also be used. A further distinction is whether the data are reproduced in anonymized form or can be associated with a company. For reasons of symmetry, data quality and data type should be consistent within a life-cycle assessment (see Section 4.3.1.1). The origin of data must always be documented. As a prerequisite for the LCA, input and output data must be acquired for each process within the assessment boundaries. Data acquisition begins with the process description.

Figure 7. Schematic diagram of a greatly simplified product line with basic structure and examples of side structure (energy, auxiliaries, and media 1 to 5) [50]

4.3.2.3.1. Process Description

The description of a process includes the following elements:

1) Site (geographic system boundary)
2) Components involved (as a rule these are components of the plant) and interfaces between the process and upstream and downstream operations (process system boundary)
3) Nature of the process (production, consumption, or disposal process; involving transformation of substances, forming, transportation, etc.), operations involved in the process, and process parameters (pressure, temperature, etc.)
4) Nature of substances and energies used; results of the process
5) Disturbances, i.e., departures from normal operation, with their duration and frequency
6) Source information

For any specific LCA, the concrete process is described. For generalized LCAs, the process description can be extracted from the literature (as it can in specific LCAs when processes are not accessible). A problem arises when average values are cited for different process sequences that lead to the same process result but cannot be traced back to individual processes. Such data may include material and energy information that does not even apply to one of the process sequences included in the average. The process description includes initial data such as the site, but it also forms the basis for further identifications, for distribution functions (Section 4.3.2.4.2), and also for the actual calculations. An adequate process description is the first step in making the inventory analysis reproducible [31], [41].

4.3.2.3.2. Acquisition of Basic Data

A precondition for the acquisition of specific basic data [41] is the early motivation of the specialists needed for data preparation who work on the processes being assessed in the companies concerned. Data acquisition includes material and substance data as well as energy data. Here "material" refers to identifiable, delimitable, and assessable matter that may consist of one or more than one substances. In this sense, a "substance" is a chemical compound or a chemical element.

The term "basic data" refers to data as acquired from companies and not transformed in any way. Basic data in original form, together with units and reference quantities, are entered in the "basic data" process table and form the basis for the inventory analysis. Some basic data can be inferred from the process description (Section 4.3.2.3.1) and are acquired in the businesses concerned when the specific inventory analysis is done. Ranges of variation of process data (inexact data) must be considered along with the frequency and duration of scheduled disturbance. Here "disturbance" denotes departures from steady-state operation, such as startup and shutdown phases. Departures occasioned, e.g., once or twice a year by readjustment of thermal production plant must be known and taken into account. Disturbances that occur more often can be compensated if data acquisition takes place over a sufficiently long time period so that the resulting errors become negligible. When no operating data can be acquired, literature data and third-party information are used as the data basis. Such data must be examined for plausibility and identified as specific or generalizing data. The age and the actual origin of these data must be considered and must be stated in every instance. When anonymized data are employed, this requirement cannot be met [31], [40].

When data varying in quality are used, or when the level of detail varies, the data must be made symmetrical; otherwise, the comparison may indicate that the worse process or even the worse total product is precisely the one for which the data depth is greatest [39]. The handling of data gaps is discussed in Section 4.3.2.4.2.

4.3.2.4. Material and Energy Balance

4.3.2.4.1. Process Balance

A "balance" is a comparison of the inputs and outputs of a process. The balance can be prepared for normal operation and for process disturbances, such as departures from normal operation. Process inputs and outputs are materials, substances, energies, and information. In the framework of the inventory analysis, a mass balance is prepared and then forms the basis for

an energy balance. The mass (material) balance is carried out on the basis of materials. A material can consist of one or more substances, a substance being a chemical compound or an element. Input materials for a mass balance include raw materials and products from upstream operations as well as secondary raw materials, auxiliaries, media, air, water, and energy resources. Output materials include the process product or coproducts, which may also be feeds to a downstream process, as well as wastes for recycling, wastes for disposal, wastewater, and waste air (Fig. 7). The forms of energy to be balanced include chemical energy, thermal and electrical energy, radiation, and noise.

The production and disposal of equipment, unless otherwise stated in the goal definition, are not considered in the LCA. Equipment itself may, however, be the object of investigation for an LCA. Here "equipment" includes machinery, buildings, tools, and other technical plant.

The space requirement, e.g., for original production (mining, agriculture, forestry, crude oil production, extraction of other raw materials, etc.) and the area used for disposal must be quantified as far as possible for the impact assessment phase, and the degree of "naturalness" must be identified ("hemerobic" levels [32]).

The material and energy balances are based on two fundamental laws, those of the conservation of mass and of energy. For each process, these imply the balance condition that the sum of the input masses m_I must be equal to the sum of the output masses m_O plus the accumulated masses m_A (Eq. 1). If there is no accumulation during the balance interval, the balance equation simplifies accordingly. Accumulation can be neglected if the balance interval includes a sufficiently large number of resettings of the plant [31], [41]. This balance condition is the prerequisite for the clarity and reproducibility of the life-cycle assessment.

$$\sum m_I = \sum m_O + \sum m_A \tag{1}$$

For the energy balance the equality of the total inputs and the total outputs is dispensed with, but not the plausibility check, because the energies are allocated as far as possible to the energy resources and discrepancies in the balance are made up by heat losses. The steps in process balancing are as follows:

1) Prepare the basic data list for materials, substances, and forms of energy (Section 4.3.2.3.2)
2) Establish the nature (process goal), mass, and unit of the process reference quantity
3) Conversion of basic data and process data to consistent mass or energy units and a consistent process reference quantity (process goal)
4) Process modeling and data correction, including the closure of data gaps [31], [41]

Figure 8. Principle of process modeling with process functions (distribution function and input ratio) [41]

4.3.2.4.2. Process Modeling and Data Correction

The basic data set generally does not satisfy the balance condition (Eq. 1). Data correction and the closure of data gaps are accomplished with distribution functions, which are written in the form of a consistent system of equations for each process. The system of equations is normalized to the process reference quantity (e.g., 1000 kg of process product). The equations are linear approximations to the actual process sequence

within certain constraints that represent the dependences of the output material streams on the input material streams as well as those between input material streams (Fig. 8). In order to write the system of equations, the process in question must be known as well as possible. The equations are based on the real process steps, e.g., on chemical reactions, and on material distributions occurring in practice. They cannot, however, reflect the actual process steps as they are influenced by various process parameters, such as pressure and temperature. A process simulation is too expensive for the majority of processes and would not adequately improve the result of the inventory analysis [41].

As the balance condition is the basis for the clarity and reproducibility of the LCA, process modeling cannot be dispensed with if the model of the inventory analysis is to be used for optimization calculations and sensitivity analyses.

For inexact data, such as averages with their associated ranges of validity, no computational rules have yet been devised for integrating this type of data in the inventory analysis. Doing so would again yield results in the form of ranges. Today, all that can be done is to calculate with averages or with best-case or worst-case alternatives. Each of these three approaches fails to reflect reality, since there is no product line in which just one of the assumptions applies to evey process. It must be supposed that computational rules will soon be developed such that inexact (fuzzy) data can be used in inventory analyses [39].

4.3.2.5. Allocations

In the data acquisition process, balance data are first related to the respective processes (process allocation), then to the object of investigation (system allocation). On the basis of the functional unit, the unambiguous balance boundaries for the system are determined, including their extensions for complementary goods. The functional unit, as a type of normalization basis, ensures that the benefits due to the several systems are equal, which is the prerequisite for comparability (Section 4.3.2.5.4). No balance data are allocated to the functional unit.

Figure 9. Schematic product line for product Pr with inlet and outlet secondary raw materials (SM 1, SM 2)

4.3.2.5.1. Process Product and Coproducts

Process allocation is performed for processes whose material flow is directed toward the object of investigation (production processes) – the process product. For processes whose main material stream is directed away from the finished product (post-consumption processes and disposal processes for production), allocation is to the input to be reclaimed or treated [41].

When processes generate more than one process product (i.e., coproducts) or take as inputs more than one upstream product to be recycled or treated, there is more than one process reference. The allocation of material and energy streams and thus of environmental burdens up to this process must be split among all the coproducts. The share of process product x (Sx) should preferably be in proportion to the masses of process products of the respective process (Eq. 2). This splitting method, which is crucial for the result of the inventory analysis and thus for the LCA, cannot be done according to masses for every process that yields coproducts. Splitting

by volume, energy content, and possibly other physical quantities is also possible [43]. The selection of the governing quantity must be done in a justifiable and traceable way. For processes where the process reference is on the input side and there is more than one upstream product, splitting is done similarly to the coproduct case.

$$S_x = \frac{m_x}{\sum_{\forall i} m_i} \tag{2}$$

where m_i is the coproduct of the process under consideration.

4.3.2.5.2. Object of Investigation

The following method is used to allocate balance data to the object of investigation. For each pre-consumption process, the mass of the pre-product for process $i-1$ (counting from the object) is divided by the mass of the product from process i. Qualitatively, the process product of process i becomes the pre-product of process $i-1$. Starting from the object of investigation, the "quantity multiplier" QM for the n-th process is the product of all the quotients from the pre-consumption processes, from manufacture of the object of investigation up to the n-th process (Eq. 3). All data for this n-th process are multiplied by the previously determined multiplier to determine the contribution of this process relative to the object of investigation. In the case of processes whose material flow is away from the object of investigation, the quotients for determining the quantity multiplier are formed in a different way: the mass of the process product of the preceding processes $i-1$ is divided by the corresponding input mass of process i (Eq. 4). The process goal, in contrast to production processes, is directed toward the pre-product. Qualitatively, the process product of process $i-1$ becomes the pre-product of process i. Processes of additive environmental protection in the area of preconsumption, or processes for generating energy and producing auxiliaries and media in the area of post-consumption, have quantity multipliers that are calculated with appropriate mixed forms of Equations (3) and (4) [41].

$$\mathrm{QM}_{n,\,\mathrm{pre-consumption}} = \prod_{i=1}^{n} \frac{m_{\text{pre-product of the following process } i-1}}{m_{\text{process product of process } i}} \tag{3}$$

$$\mathrm{QM}_{n,\,\mathrm{post-consumption}} = \prod_{i=1}^{n} \frac{m_{\text{process product of the following process } i-1}}{m_{\text{pre-product of process } i}} \tag{4}$$

In this way the material and energy data of all processes within the product line are allocated to the object of investigation. The further environmental burdens resulting from the production of complementary goods to guarantee equality of benefit (Section 4.3.2.5.4) are determined by the same rules and added to the environmental burdens of the product line of the object of investigation. This is how, in the framework of the functional unit, with the exception of the case of open-loop recycling (Section 4.3.2.5.3), the environmental burdens are determined for which the impact potentials are found in the classification and characterization steps.

4.3.2.5.3. Open-Loop Recycling

Open-loop recycling is characterized by a secondary material leaving the balance system or a secondary material entering the balance system, and similarly for energies. Figure 9 shows a product line with the product Pr, the primary benefit of the system, taken as the object of investigation. After consumption, a secondary raw material SM_2 is generated by recycling associated with the product line. This secondary material is reused not in the same product line but in another, unknown, product line. For consistency in the handling of this additional benefit (secondary benefit) supplied by and leaving the system under consideration, the material and energy streams and thus the environmental burdens found in the LCA are those that would occur if this secondary material were produced from primary raw materials (Eq. 5). To this end, the masses m of primary raw materials (RM) as well as wastes and emissions (WE) arising in the respective time intervals are used, namely $(t_p - t_0)$ from extraction of raw materials to production and $(t_\infty - t_0)$. As shown in Equation (6), the sum of the environmental burdens (EB) so produced but not yet weighted with the impact potentials (see Section 4.3.3) are subtracted from the environmental burdens of the product line under

consideration (m_{Pr}) [44]. Similar formulas apply to energies.

$$m_{\mathrm{SM}} = \sum_{t_0}^{t_{\mathrm{P}}} \sum_{i} (m_{\mathrm{RM}} + m_{\mathrm{WE}})_{t,i} \tag{5}$$

$$EB_2 = \sum_{t_0}^{t_\infty} m_{\mathrm{Pr}} - \sum_{t_0}^{t_{\mathrm{P}}} m_{\mathrm{SM}_2} \tag{6}$$

Also shown in Figure 9 is a secondary raw material SM_1 entering the balance system. It is not known what environmental burdens arose in the production of this secondary raw material. For consistency in balancing, the environmental impacts are determined for the case that this secondary raw material is produced from primary raw materials. The environmental burdens so determined for the secondary raw material are added to the environmental burdens of the product line (Eq. 7). For the case where the secondary raw material SM_2 leaving the system is equal in quality and quantity to the secondary raw material SM_1 entering the balance system, the pluses and minuses in the environmental burden calculation would offset one another. This represents the ideal case of closed-loop recycling [44]

$$EB_1 = \sum_{t_0}^{t_\infty} m_{\mathrm{Pr}} + \sum_{t_0}^{t_{\mathrm{P}}} m_{\mathrm{SM}_1} \tag{7}$$

Only when the secondary raw material replaces a material can one speak of recycling, and only then can these allocation rules be applied in a methodologically correct manner.

4.3.2.5.4. Equality of Benefits

The functional unit is intended to ensure equality of benefit between the systems under consideration [42], [45]. This happens in the product life-cycle assessment based on the product used for comparison. Systems being compared must be equal in benefit; this means, among other things, that products being compared must meet the same requirement profile to have equal primary benefits. Equality of benefit exists in relation to the objects of investigation provided there is no additional benefit (secondary benefit).

Additional benefit is created, in particular, by recycling processes, but also during the primary production of byproducts (e.g., steam) that cannot be allocated by simple coproduct relations (Section 4.3.2.5.1). In the case of open-loop recycling (Section 4.3.2.5.3), e.g., an additional benefit is created by the secondary raw material SM_2 (Fig. 9), and this additional benefit is not taken into account by the product as reference quantity. Equality of benefits between systems exists when the sum of goods produced in each system is equal in quantity and quality. For this to be so, the system must be expanded to include the processes for producing the so-called complementary goods C of equal quantity and quality from primary raw materials (Fig. 10). Only by this procedure are systems that have the same primary benefit but are not equal in benefit because of the secondary products produced (Eq. 8) rendered comparable (Eq. 9) and thus satisfy the functional unit.

$$\mathrm{A}_1 \cup \mathrm{B}_1 \neq A_2 \tag{8}$$

$$\mathrm{A}_1 \cup \mathrm{B}_2 = \mathrm{A}_2 \cup \mathrm{B}_\mathrm{C} \tag{9}$$

Figure 10. Expansion of system to render noncomparable systems comparable [42]

What is compared is not the benefits of the systems – these are equal – but the environmental burdens generated by systems of equal benefit.

Table 10. Some indicators [30], [32], [47], [51–53]

Heading	Indicator (reference substance)	Spatial relevance
Resource consumption		global
Renewable resources	area required, biotic depletion factor	
Nonrenewable resources	range, abiotic depletion potential	
Greenhouse effect	global warming potential (CO_2)	global
Ozone depletion	ozone depletion potential (R-11)	global
Acidification	acidification potential (SO_2)	continental/regional
Eutrophication	nutrification potential	continental/regional
Terrestrial	(nitrogen)	
Aquatic	(phosphate or COD)	
Photochemical smog	photochemical ozone creation potential	
	(ethylene)	regional
Human toxicity	human toxicity potential	continental/regional
Ecotoxicity		continental/regional
Terrestrial	terrestrial ecotoxicity potential	
Aquatic	aquatic ecotoxicity potential	
Area used/species diversity	m^2 (hemerobic levels)	regional/local
Odor	odor threshold value	local
Noise	acoustic level in $Pa^2 \cdot s$	local

4.3.3. Impact Assessment

In the impact assessment step, potential environmental burdens of the quantities of materials and energies determined in the inventory analysis are aggregated on the basis of scientific analyses of environmental processes [46]. For practicability and feasibility, materials and substances are rendered comparable in potential impact by being allocated to a category and thus given the same unit so that they can be aggregated. Actual impacts on the environment due to the systems (product lines) being compared are not determined. The purpose in determining the impact potentials is to eliminate subjective effects in classification and characterization. According to SETAC (Society of Environmental Toxicology and Chemistry), these two operations are described as follows [28]:

1) Classification: selection of the impact categories (headings) for examination and allocation of inventory analysis data to a comprehensible number of headings (Table 10)
2) Characterization: definition of scientific units of measure or indicators for each heading

With the indicators chosen, the inputs and outputs are then recalculated as impact potential quantities, which are aggregated in the " ecoprofile of products."

4.3.3.1. Classification

In classification, data from the inventory analysis step are allocated to "headings" [28] and the decision is made as to what headings will be used in the life-cycle assessment [47]. The allocation of cumulative resource consumptions and emissions over the life cycle to concrete environmental problems is intended to give a more direct relationship to environmental problems and policies without restriction to individual media (air, water, soil). This approach means that aggregation can be done on a scientific basis, because the action chains for individual materials exhibit similarities that can be described in a scientific manner.

In the LCA context, various headings differing in spatial relevance are considered (see Table 10). The spatial relevance is crucial because, in concrete ecosystems, the prestress, the medial propagation capabilities, and the buffer capacities can vary widely from one pollutant to another. For this reason, the use of system inventory analysis data is methodologically dubious, particularly in the case of local and regional headings, when the spatial relevance of the inventory analysis data (geographical balance space) and the spatial relevance of the headings (Table 10) are different.

The selection of headings for consideration depends on the objective of the LCA and takes account of production-specific burdens.

4.3.3.2. Characterization

Global impact indicators for the greenhouse effect and ozone-layer damage have been developed by, respectively, the Intergovernmental Panel on Climate Change (IPCC) and the Scientific Assessment Panel under the tutelage of the World Meteorological Organization [47]. These

indicators have been acknowledged internationally.

Several impact indicators have the feature that relative impact potentials are stated in comparison with a reference substance. This is especially so for LCAs covering large geographic areas (country, continent). Here the ecosystems, organisms, and receptors involved and the conceivable propagation paths for substances (given their different conversion reactions and action mechanisms) are so diverse that the concrete impact can no longer be described. What is more, the specific impact cannot be the goal of an LCA; this is a contrast between LCA (lessburdens-are-better approach) and environmental compatibility testing (only-burdens-above-threshold-are-considered approach). The extension to actual impacts is not possible with the existing indicators. Uncertainties and limitations of the environmental indicators must be considered in their interpretation.

The indicators of the headings should be free of normative and political considerations. The following parameters are to be taken into account [48]:

1) Harm (to human beings, fauna, flora, buildings, the ozone layer, etc.)
2) Persistence in the environment
3) Mobility (danger of long-lived emissions becoming spread over large areas)
4) Accumulation in the environment
5) Synergisms/antagonisms or reactions with other substances (e.g., formation of photochemical smog)

Action chains and feedback mechanisms must also be examined whenever possible (Fig. 11).

Figure 11. Example of an action chain [49]

For example, the action chain for the greenhouse effect can be described as follows [50]:

– Various activities, such as burning of fossil fuels, lead to
– Emission of gases, which have various
– Primary effects. They can directly or indirectly absorb IR radiation and thus upset the equilibrium between energy absorption and energy emission.
– The secondary effect is a rise in the mean temperature of the Earth.
– Tertiary effects exhibit geographic dependences: melting of ice, rise in sea level, drought, etc. Further consequential impacts include changes in the composition of vegetation.

This example makes it clear that the impacts at the beginning of the action chain are chemical or physical in nature, while the derivative impacts are biological and may be functions of geographic location. Quantification becomes more difficult down the action chain, so that the definition and precise demarcation of the heading is important. The indicator should bear on a "node" in the action chain (on the secondary effect in the above example). Table 10 summarizes some of the indicators developed to date and shows the spatial relevances of the headings.

The reductionist approach of [54] restricts itself to a few parameters for simplicity's sake: consumption of renewable and nonrenewable energy, consumption of minerals and water, wastes (classified as municipal, hazardous, and radioactive), global warming potential, ozone depletion potential, acidification, and eutrophication. The last four of these indicators are described below.

4.3.3.2.1. Greenhouse Effect

The heating m_j of atmospheric layers near the surface of the Earth when long-wavelength radiation emitted from the surface is absorbed by greenhouse gases is described by the global warming potential (M_{GWP}) of all greenhouse substances [30]:

$$M_{\mathrm{GWP}} = \sum_{\forall j} m_j \cdot \mathrm{GWP}_j \tag{10}$$

The direct global warming potentials GWP_j of various infrared-absorbing substances are stated

relative to CO_2 for an integration time of 100 years:

$$\mathrm{GWP}_j = \frac{\int_0^{100} a_j c_j \mathrm{d}t}{\int_0^{100} a_{\mathrm{CO_2}} c_{\mathrm{CO_2}} \mathrm{d}t} \tag{11}$$

where a_j is the absorbing power and c_j the concentration of substance j at time t.

4.3.3.2.2. Ozone Depletion

The decline in the stratospheric ozone concentration is described by the ozone depletion potential (ODP), which is the ozone destruction efficiency relative to R-11 ($CFCl_3$). This value is determined in one- or two-dimensional computer simulations [49], which are necessary because the ODP is governed by physical and chemical processes in the atmosphere. An upper boundary for the ODP can be calculated from the relative quantity of chlorine that can reach the stratosphere as a result of emission of a gas (chlorine loading potential CLP, also relative to R-11).

The Swedish Environmental Research Institute has proposed that ozone depletion should be described in terms of three separate figures – an indicator for substances containing chlorine (ODP, CLP), one for those containing bromine (ODP), and the total quantity of N_2O – until further research makes it possible to combine all this information into one parameter [49].

4.3.3.2.3. Acidification

If the acid content of soils and waters rises excessively, mineral nutrients may be leached from soils and heavy metals may be mobilized. The reference for an impact indicator of acidification (M_{AP}, where AP stands for acidification potential) is the potential of SO_2 to form H_3O^+ ions. The acid-forming pollutants included in the inventory analysis are aggregated as [30]

$$M_{\mathrm{AP}} = \sum_{\forall j} m_j \cdot \mathrm{AP}_j \tag{12}$$

This formula is based on complete oxidation of sulfur dioxide in air followed by the reaction with water (raindrops, atmospheric water vapor), yielding 2 mol of H_3O^+ per mole of sulfur dioxide [30]. To allow for the difference in activity between substances j, it must be taken into account that the loss of a hydrogen ion is an equilibrium reaction described by a substance-specific acidity constant K_{S}, and that the fraction of H_3O^+ ions liberated is a function of pH [55]. The relative acidification potential is then found by dividing n_j, the number of moles of H_3O^+ liberated per mole of substance j, by the number $n_{\mathrm{SO^2}}$ of moles of H_3O^+ per mole of SO_2:

$$\mathrm{AP}_j = \frac{n_j}{n_{\mathrm{SO_2}}} \cdot \frac{64}{M_j} \tag{13}$$

4.3.3.2.4. Eutrophication

If additional nutrients are introduced into soils and waters, excessive growth of certain species (e.g., algae) can disturb the ecological equilibrium. The action of eutrophying substances M_{eu} is determined by aggregating as follows [30]:

$$M_{\mathrm{eu}} = \sum_{\forall j} m_j \cdot \mathrm{NP}_j \tag{14}$$

The eutrophication of substances (where NP stands for nutrification potential) shows a strong receptor dependence. In terrestrial ecosystems, the deficiency of nitrogen for eutrophication is dominant [49], so that nitrogen emitted into the air must be converted to nitrogen equivalents (molecular mass of nitrogen = 14):

$$\mathrm{NP}_{\mathrm{terr},j} = \frac{n_j \cdot 14}{M_j} \tag{15}$$

where n_j is the number of nitrogen molecules in substance j.

In aquatic ecosystems, the controlling parameter for eutrophication is oxygen depletion. In addition to direct oxygen consumption in the degradation of organic materials, a second problem is the indirect oxygen demand for the degradation of biomass built up via the emitted nitrogen (deficiency factor in marine ecosystems) and phosphorus (deficiency factor in limnetic ecosystems). For the biomass generated, it is assumed that the formation of one mole of biomass requires 16 mol of nitrogen and 1 mol of phosphorus [49].

4.3.4. Interpretation

The steps of classification and characterization help to reduce the number of substances and energies identified in the inventory analysis to an easily handled number of headings for each product investigated. If there is no one product that has better values than another in all the headings, determination of the ecologically "better" variant requires an interpretation so that the results found in the various categories can be combined.

4.3.4.1. Objective and Requirements

The purpose of the interpretation step is to apply objective scales to arrive at a relative weighting of the results obtained in classification and characterization, as well as inventory analysis results that cannot be put in the form of action potentials [27]. The DIN standard points out that an interpretation justified in purely scientific terms is not possible and any valuation must have a political aspect. This means that the interpretation must integrate scientific scales with political environmental quality goals. These goals or targets are embodied in international conventions (Agenda 21, the Rio Declaration, the biodiversity treaty [56], [57], etc.), human rights, principles of environmental protection (precautionary principle), and national initiatives.

The interpretation step is intended to provide further aggregation of the data so as to reduce the complexity of environmental burdens and thus serve as an aid to decision-makers. Interpretation does not constitute a decision.

Interpretation makes it possible to arrive at subjective assessments in a context-independent, reproducible, scientifically sound way, as well as to generate subjective, context-dependent assessments. The methods of interpretation must satisfy strict requirements as to clarity, reproducibility, plausibility, and discussability. Subjectivity in interpretations does not mean arbitrariness; it rather expresses an awareness that scientific knowledge of the complex relationships prevailing in the environment is limited.

4.3.4.2. Interpretation Approaches

There is as yet no consensus on interpretation methods [29]. Three main lines are recognized:

1) Normalizing, quantifying assessment
2) Verbal-argumentative assessment
3) The reductionist approach

Mixed forms of normalizing-quantifying and verbal-argumentative assessment are applied where the aspects that cannot yet be quantified are interpreted by verbal-argumentative techniques.

4.3.4.2.1. Normalizing, Quantifying Methods

The assessment of environmental factors by quantitative normalizing methods is carried out by means of a model and by using limit values [58], quality targets [59], degrees of goal fulfillment (utility analysis) [60], critical loads [55], [61], loss – benefit analysis [62], monetarization [63], and so forth. These methods can be classified as follows:

1) Single-index methods [29] that yield, at the end of the valuation, a number representing the (possibly relative) environmental burdens of the items compared
2) Partial aggregation methods in which the environmental burden is expressed in terms of several parameters
3) Methods regarded as single-index or partial aggregation techniques but omitting the classification and characterization steps

Indicators derived in classification and characterization can be directly weighted and aggregated into a single index by using utility analysis with quantitative degrees of goal fulfillment [60] or by attempting a quantitative operationalization of the notion of "sustainable development" [55]. To date, however, normalizing, quantifying interpretation methods have mostly employed one of the two BUWAL concepts: aggregation to four parameters (critical quantities of air and water, specific landfill volume, energy equivalence [58]) or to one parameter (" ecopoint" method [59]); this has been used most often in LCAs not requiring a classification and characterization in the sense of SETAC [28]. The critical

volumes are the theoretical quantities of air and water that would be required to reach the politically specified limit for substance *i* by dilution (Eq. 16). These quantities do not represent impact potentials but must be understood as pure computational values for orientation. The energy equivalence value references all forms of energy to the primary energy used. The "ecopoint" method based on this applies " ecofactors" (Eq. 17) to reduce the environmental burden to a single parameter (Eq. 18). The "critical flow" in the denominator is the politically specified maximum permissible burden for the assessment space (e.g., Switzerland) and does not represent the real impact potential. Alternatively, the scientifically derived "critical loads" [61] could be used to determine the ecological shortage [55]. Critical loads are the estimated pollutant exposures, derived from scientific models, such that no perceptible changes in ecosystem structure and function are anticipated according to present knowledge. Among the objects for comparison, the one with the lowest ecopoint number is deemed the most "environmentally friendly."

$$\text{Critical volume} = \sum_{\forall i} \frac{\text{Emission}_i}{(\text{limit value})_i} \tag{16}$$

$$\text{Ecofactor} = \frac{\text{present pollutant flow in assessment space}}{\text{critical flow}} \cdot \frac{\text{dimensional factor}}{\text{critical flow}} \tag{17}$$

$$\text{Ecopoint} = \sum_{\forall j} (\text{Ecofactor} \cdot \text{Emission})_j \tag{18}$$

4.3.4.2.2. Verbal-Argumentative Assessment

In verbal-argumentative methods [64], predefined goals and interpretation criteria are applied in an attempt to assess the relative ecological weights of the headings on the basis of well-defined environmental goals. To ensure the reproducibility of verbal-argumentative methods, a qualitative (i.e., described merely in verbal form) utility analysis is employed as a structuring aid.

The starting point for a verbal-argumentative assessment is often a normalization, which may be done either with the "fir tree" representation [65] or by normalization [30], [66] of the impact indicators. The tree diagram is based on the magnitude ratio of the action indicators of the comparison object. A branch of the tree is plotted only for the comparison object that shows greater burdens under this category. In normalization, the magnitudes of the impact indicators are referred to the total for this heading for a certain region (global [66] or national [67]) and a certain time interval (year). Normalization can also be performed as part of the classification and characterization steps.

On this basis, the interpretation can be performed outside or inside the area of responsibility of the party carrying out the life-cycle assessment. Techniques available are Delphi, expert hearings, ranking, and so forth [68–70]. The most advanced of these are the UBA (German Federal Environmental Agency) method [65] and analogous procedures for European "ecolabeling" (without classification and characterization) [71]. The first step in these methods, weighting, is done similarly to normalization: in terms of the specific contribution or the production intensity (PI) factor. These quantities reflect the difference from one product group or sector to another in relevance to the corresponding national or European total emission. Next, the ecological significances of the headings or substances are determined, discussed, and evaluated on the basis of definite criteria. The UBA method uses the following criteria: ecological hazard potential, reversibility, spatial relevance, environmental preferences of the public, and relationship of the prestress to quality goals. These two factors (specific contribution versus PI factor and significance factor) are combined in a verbal-argumentative manner to reflect the weighting of the categories. Now, for each comparison object, it is determined how much of the relative disadvantage in an impact category or heading (symbolized by the presence of a branch in the fir tree model) can be offset or even priorized by the relative advantage in another category. The procedure for deriving the ecological significance is under scientific discussion and a topic of ISO and DIN activity.

The verbal-argumentative interpretation method expresses weights in the form of words (slight, moderate, great significance, etc. [65]), symbols (+, −) [72], letters (ABC weak-point

analysis, where A = critical, B = may be critical, C = noncritical) [33], or numbers.

4.3.4.2.3. Reductionistic Approach

Because there is no consensus on interpretation, this step is sometimes omitted altogether (along with classification and characterization) [73], or only a subset of the inventory analysis is considered, such as resource consumption [74] or ecotoxicity [75]. The reasons are that although quantifying-normative methods do offer the advantages of systematic character and reproducibility along with a transparent and easily comprehended representation of results, at the same time they have the disadvantage of an illusory reliability and the apparent unambiguity of the results, especially with single-index methods. Verbal-argumentative methods lack these disadvantages but are not reproducible because of their subjective elements.

If interpretation is dispensed with, at least a weak-point analysis can be carried out to identify "ecological hot spots." Sensitivity analyses can aid the evaluation of optimization proposals. Inventory analysis and impact assessment by themselves will be important aids to decisionmakers [31].

The reduction of the ecological analysis to resource consumption is justified by the essential impossibility of "scientifically studying . . . or quantifying . . . all chemical, physical, and biological impacts on ecosystems, even for a single substance released into the environment." Instead, the material or area intensity per service unit is used as the sole decision parameter. In this treatment, all materials and areas used are added together in an undifferentiated manner, i.e., without classification and characterization and without regard to present knowledge of toxicity and other environmentally relevant aspects [74].

4.3.5. Improvement Assessment (Optional)

According to SETAC [28], it is only in the improvement assessment phase that options for reducing environmental impacts are identified and evaluated. The study of ecological optimization can be done by comparing several options (e.g., alternative processes) or performing a sensitivity analysis if the functional relationships have been modeled (see Section 4.3.2.4.2). According to DIN [27], the optimization step can also be carried out as part of the inventory analysis if what is desired is a reduction in, e.g., the consumption of special raw materials or the emissions of certain substances. Ecological optimization, according to DIN [27], is done in the context of interpretation.

4.4. Critical Review

To determine whether the specifications set down in goal definition and scoping have been met, the method has been properly applied, and the data used are plausible, a critical review is carried out. The selection of the examiner is important for plausibility checking of LCA results. For life-cycle assessments within the company, an employee can perform the review. In the case of public LCAs, the examiners must be selected from among interested circles. The review can take place in parallel with the LCA or after it has been completed. To save time and avoid duplication, parallel review accompanying LCA performance is preferable to post-assessment review.

The parallel critical review takes place in the following phases of the life-cycle assessment:

1) At the beginning, to verify the selected functional unit and the system boundaries as well as the planned volume of data and the desired data quality. In public LCAs, an additional purpose is to involve the technically qualified public early (including circles with ecological, social, and economic interests) and promote acceptance [27].
2) After the first data collection and modeling, to check the specific method used and also to pick up hints for subsequent processing.
3) At the final report stage, to check the whole LCA (including conclusions) for plausibility [28].

5. Waste Management in the Chemical Industry

5.1. Introduction

The central function of the chemical industry is the economical transformation of substances into products desired in the market. This transformation should take place with a yield as close to 100 % as possible, but there is always a percentage of undesired products, which are collected under the term "residues."

A second important task of the chemical industry is to minimize the impacts of residues on the environment as far as is technically feasible. To carry out this task, the industry employs waste-management concepts which encompass waste avoidance by avoiding or reducing the quantity of residues and the recycling of residues, as well as the disposal of the remaining residues as "waste." Avoidance, reduction, and reclamation take priority over disposal by incineration and landfilling. A final task of waste management is avoiding or reducing the quantity of production wastes and disposing of them safely.

In the downstream processing, conversion, and consumption sectors, some product becomes waste, and this is referred to as "product wastes" to avoid confusion with production wastes. Recycling of product wastes is acquiring greater importance and is becoming a further waste-management function in the chemical industry.

5.2. Chemical Industry Wastes

The industrial production sector in Germany generated 259.1×10^6 t of waste in 1990 [76]. This included 8.95×10^6 t of waste requiring special monitoring, which is also referred to as hazardous waste. In the same period, the German chemical industry, as part of the production sector, generated 8.06×10^6 t of waste [76], including 2.7×10^6 t of hazardous waste. The broad production spectrum of the industry means that the wastes are also very diverse in terms of chemical composition and consistency. This is illustrated by the following list of the most important wastes (1990, in 10^3 t) [77]:

Sewage sludges, sludges from wastewater and water treatment (dry basis)	1174
Building rubble, excavated soil, pavement rubble without harmful contaminants	1159
Wastes from energy production (slags, ashes, filter dusts)	883
Red mud	759
Residential-type commercial waste (incl. used paper, packaging, industrial sweepings)	522
Building rubble, excavated soil, soils with harmful contaminants	331
Gypsum wastes with harmful contaminants	312
Inorganic acids, acid mixtures	278
Gypsum/lime mud with harmful contaminants	235
Sludges from precipitation and solution processes with contaminants	201
Organic solvents and solvent mixtures containing halogenated solvents	131
not containing halogenated solvents	145
Filter aids and absorbents with contaminants (kieselguhr, activated carbon, activated earths)	144
Organic distillation residues containing solvents	128
Carbide sludge with no harmful contaminants	73
Barium sulfate sludge and rock-salt residues (gangue)	63
Plastics wastes	61
Packaging material with harmful contaminants	40
Wastes from plastics manufacturing and converting	32
Lime and gypsum mud with no harmful contaminants	22
Oil and gasoline separator contents	14
Organic dyes	12
Plastics slurries	12
Aliphatic amines	11
Filter dusts containing nonferrous metals	11
Sludge from tank cleaning	9
Other wastes	1298
Total	*8060*

Over half the quantity of wastes is accounted for by three large groups: 29 % wastes not associated with chemical production (building rubble, excavated soil, wastes from energy production facilities); 15 % from wastewater and water treatment; and 15 % inorganic sludges.

This quantitative information represents a waste balance which deviates from the waste statistics, and is defined as follows [76]:

1) Duplication is removed by subtracting wastes accepted by other businesses, and secondary wastes generated in waste treatment (e.g., slag and ash from incineration)
2) Quantities delivered by waste producers to reprocessors or scrap dealers (i.e., residues) are not included
3) Sewage and water-treatment sludges are reported on a dry basis because of their high water content

Comparable statistics broken down in a similar way are not available for the chemical industries of other countries.

5.3. Waste-Management Concepts

5.3.1. Residues and Wastes from Production

A chemical production process generates residues in addition to the intended end product. These residues can be recycled (Fig. 12). If recycling is impossible for technical or economic reasons, residues become waste. In addition, polluted wastewater and waste gases can be formed. Disposal of wastes includes incineration and landfill disposal. Waste incineration generates secondary wastes in the form of slag and ashes, which have to be utilized or disposed of. Wastewater is produced in waste-gas scrubbing. The treatment of wastewater leads to the formation of clarifier and other sludges, which must then be disposed of as waste. Landfill leachate must also be treated, and once again this process can contribute to sludge formation. In this way, a complex residue/waste system results, and the solution of one problem results in the formation of secondary waste [78].

5.3.2. Production-Oriented Management

Residues and wastes can arise in more than one environmental area of production. Concepts for residue management must therefore extend over many such areas. Disposal of residues as wastes, considered alone, even if carried out in an appropriate, environmentally compatible form, has the disadvantage that the waste problem is dealt with at the end of the production chain; there may also be ecological and economic drawbacks associated with this arrangement. These end-of-pipe technologies are generally more expensive than upstream measures (see also → Production-Integrated Environmental Protection).

Waste management in production is a planned, purposeful technique including three elements [79]:

1) Analysis of wastes and waste production by type and quantity in the production chain. This makes it possible to device an "avoidance" concept.
2) Environmentally compatible technical measures (disposal) or new solutions for the waste problem on the basis of the analyses.
3) Monitoring of the practices implemented.

Today, the principle of waste avoidance is incorporated in new process development (efforts to avoid generating residues or decrease the quantity generated). Existing processes are also studied and reconfigured if appropriate. This is the principle of production-integrated environmental protection. Another way to implement this principle is to utilize residues; the relative priority of utilization and waste disposal has to be established case by case. The ecological and economic effects of utilization have to be analyzed; one question is whether reclamation of materials may harm the environment more than it helps, for example when recovery processes consume disproportionate amounts of energy. Again, many reclamation processes generate wastes, wastewaters, and waste gases, which in turn must be disposed of. Finally, a reclamation process cannot be repeated indefinitely, and utilization has to be viewed from the market standpoint. Accordingly, it is necessary to clarify in advance whether the reclaimable substance is required and accepted by downstream processors or consumers. Problems can arise when the new material obtained by reclamation is of lower quality than the primary product. If there is no market, even the best reclamation concept is doomed to fail. Even a viable reclamation concept can come to nothing if the level of acceptance changes abruptly. The decision between utilization and disposal must also take account of ecological balances prepared by scientifically sound and objective methods. This statement also holds for thermal utilization, which ranks equally with recycling of substances: A residue is thermally utilizable if its combustion produces

Figure 12. Principles of chemical production processes

more heat than the sum of the losses experienced. The difference between the heating value of a substance and the unavoidable losses in combustion can be recycled to the production process in the form of steam and electric power. This energy replaces primary energy sources such as coal, petroleum, and natural gas. If the energy balance is zero or negative, however, thermal treatment becomes a form of disposal.

Because residue reduction and reclamation cannot lower the quantity of production waste to zero, environmentally sound disposal will remain the basis of waste management for the foreseeable future. Disposal takes the form of incineration or landfilling. Each of these activities today meets high technological and safety standards and ecological concerns are amply addressed. Emissions into air, water, and soil have been cut to a very low level. A modern disposal concept also includes analysis of the present quantity, makeup, and properties of the waste and waste streams along with short-term projections. Whenever possible, secondary wastes such as ash and slag produced by incineration are also utilized, and the heat produced is reclaimed in the context of energy recycling.

5.3.3. Product-Oriented Management

When products of the chemical industry are processed and consumed, they are partly converted to waste. A reduction of such product wastes is necessary and can be achieved through recycling of product wastes or the formation of closed loops [80]. The chain of responsibility from producer via downstream processor and consumer must also be completed under a "holistic marketing" concept [81]. This means considering what happens to the material after use. The technical reclamation measures have to be matched to each type of product waste.

Recycling can involve recovery of raw materials by chemical cleavage or reclamation of materials with no alteration of chemical structure. It is necessary to verify that necessary cleaning, transport, and energy do not lead to ecological impacts elsewhere. Reclaimed product wastes should always fill gaps in the market and help to save costly raw materials; they should not be justified solely by recycling for its own sake. Again, market conditions must not be left out of account, and the technical constraints on the reclamation of product wastes must be taken into consideration. Plastics wastes, for example, are not indefinitely recyclable without change in composition, because the recycling processes alter the molecular structure. The structural changes

in turn affect macroscopic properties of the plastic, such as toughness and strength. The recycling system takes the form of a cascade ("downcycling") that ends in the irreversible transformation of matter to energy by combustion with utilization of the energy, or disposal in landfills.

5.4. Disposal Measures

5.4.1. Logistics

Analytical studies are used to monitor and control production processes in the chemical industry and to characterize chemical products for their later use. The same holds for wastes and waste-disposal processes.

Any residue that is not utilized in the production plant is characterized by an extensive list of chemical and safety data. This information is used in assessing the behavior of the waste during shipping, storage, and disposal, and also serves as a guide for selecting the appropriate disposal method. Studies of the physical and chemical properties of wastes are performed and their exact compositions are determined. Data on the production process that gives rise to the wastes are also integrated into the process. A product-by-product breakdown of waste quantities is obtained on the basis of a production registry. In this way, when production changes are planned, the resulting changes in waste streams can be predicted as well.

When wastes are to be disposed of in landfills, a variety of parameters are ascertained by analysis of the original substance and analysis of the aqueous eluate. Other studies are related to landfill emissions such as leachate.

Some special parameters (e.g., flash point, heating value, water content) must be determined for wastes that are to be disposed of or thermally utilized by combustion. All data for a given waste are documented in a multi-page survey form. The plant manager is responsible for the correctness of the information. After thorough checking, including a check for completeness of analysis data, the necessary pretreatment and the disposal route (including the proper transportation method) are decided on by a cental corporate office. Disposal and transformation are only carried out when official approval has been obtained for each individual case. Computer-based systems are used to document all analytical data on wastes, calculate disposal costs, and provide data to the regulatory agencies.

5.4.2. Waste Combustion

Hazardous Wastes. Incinerators are used for solid, pastelike, and liquid wastes that cannot be placed in landfills because of environmentally relevant constituents, provided they can burn without exploding. Such wastes are essentially organic production residues, vegetable and animal fat products, herbicides and pesticides, petrochemical and coal products, organic solvents, dyes, paints, adhesives, putties, and resins. To avoid harmful emissions when these products are combusted, the flue gases must be cleaned.

Before initial delivery, each waste must be examined as to its relevant physical and chemical data. The purpose of this analysis is to make certain that the emission limits as well as occupational health and safety and fire-protection standards are not violated upon combustion. The results of this investigation make it possible to classify wastes, that is, to group them with respect to the combustion process and thus achieve optimal furnace conditions.

Widely used combustion systems include rotary kilns, fluidized-bed furnaces, and multiple-hearth furnaces. A number of wet and dry processes have been devised for cleaning the flue gases. Hot flue gases are cooled and their energy is recovered and used to raise steam before the cleaning stage.

At BASF, flammable solid, pastelike, and liquid residues are combusted in eight furnaces. Each combustion unit consists of a rotary kiln with afterburner chamber and a steam boiler. The superheated 18-bar steam from units 1 to 6 is fed into the BASF plant network. In units 7 and 8, a higher-value steam is generated with an efficiency of ca. 74 % and supplied to a back-pressure turbine, where it is expanded from 43 bar to 5 bar. To utilize the heat of the flue gases between 300 °C and 180 °C, a waste-heat boiler was installed to raise 5-bar steam. Electric power and 5-bar steam are fed into the respective plant systems.

Three flue gas cleaning units were built for the eight rotary furnaces. Each unit consists of

an electrostatic filter and a three-stage scrubber. By 1996, these units will be retrofitted with catalysts to lower NO_x emissions and degrade dioxins. The plant combusted ca. 150 000 t of waste in 1992; on reconstruction, a combustion capacity of 175 000 t/a will be available after 1996 [82].

The Hoechst waste combustor at the Höchst plant has a capacity of ca. 45 000 t/a. The system also consists of rotary furnace, afterburner, electrostatic filter, and flue-gas scrubber. A coke filter has been retrofitted to cut dioxin emissions, and an SCR unit is attached to the filter to reduce NO_x. Scrub liquor is forwarded to a wastewater treatment system for heavy-metal precipitation and then to the plant's biological treatment facility.

Bayer operates a number of similarly engineered waste combustion units. At the Dormagen plant, a further combustor for solid and liquid wastes has been placed in service. It consists of a rotary furnace, afterburner, waste-heat boiler, and gas scrubber. The plant incorporates a condensation-type electrostatic filter specially developed by Bayer [83] and an SCR unit for selective catalytic reduction of nitrogen oxides (with ammonia) and for degradation of dioxins in the tail gas (see Fig. 13).

Sewage Sludges. At BASF, ca. 100 000 t/a of sludge (dry basis) is dewatered to ca. 40 % dry content. This consists of excess sludge from the biological wastewater treatment system mixed with coal and ash (filter aids). The filter cake is combusted in fluidized-bed units with a positive energy balance. The heat liberated by combustion in the furnaces is used to raise steam. Flue-gas cleaning consists of dust removal with an electrostatic filter and wet scrubbing [82]. The multiple-hearth sludge combustion method used by Bayer is similar (see Fig. 14). Waste gases and vapors from the multiple-hearth furnace are thermally treated in a post-combustion chamber with addition of liquid wastes [84].

Hoechst has put a two-stage sludge combustion system in service, with a capacity of 130 000 t/a. The combustion unit is a fluidized-bed furnace consisting of the fluid-bed space proper and a separate, cylindrical secondary reaction zone operated at 850 °C (see Fig. 15). The oxygen content in the fluidized bed is held between 1 and 3 vol % to lower the NO_x concentration. Both carbon monoxide and organic carbon are burned in the secondary reaction zone; preheated secondary air containing 6 – 7 vol % oxygen is injected at the head of the furnace. In this way, fuels that contain nitrogen-containing compounds (e.g., protein compounds in sewage sludge) can be burned with a much lower NO_x formation rate, eliminating the need for a flue-gas denitrification unit [85]. Flue-gas scrubbing liquor is recycled, with a substream going to a wastewater treatment unit. Heavy metals in the scrub liquor are removed there in a multi-stage process:

1) Two neutralization stages with caustic soda (precipitates sparingly soluble metal hydroxides)
2) Addition of sodium sulfide in neutralization stage (precipitates even more sparingly soluble metal sulfides)
3) Flocculation of heavy-metal precipitates with iron(III) salts and polyelectrolytes; settling and filtration

The product water is fed to the biological wastewater treatment facility.

5.4.3. Landfill Disposal of Wastes

Landfill design, the technical and organizational aspects of landfill operation, and the requirements on wastes for landfill disposal are regulated in detail by TA Abfall (an administrative regulation under the German Waste Disposal Act). The focus is protection of groundwater, which is achieved by the use of a landfill foundation seal. This feature can consist of a natural seal (e.g., a bed of clay) or an artificial liner (e.g., plastic sheeting). Leachate formed above the liner is removed through drains, collected, and forwarded to treatment. An example with an artificial seal is the Hoechst AG sewage sludge landfill (see Fig. 16). Leachate is led away via drain pipes and collected for treatment. Another landfill operated by Hoechst, for production wastes, uses a 40 m underground clay bed as its foundation seal. Leachate and precipitation are collected and sulfates are removed in a pretreatment system in which sulfate is precipitated as gypsum. The treated leachate is then forwarded to biological treatment.

For its Leverkusen landfill, Bayer devised new intermediate and cap seals. Textured plastic webs functioning as space-saving intermediate seals form an effective barrier to prevent precipitation penetrating into the wastes until the cap is placed. Each intermediate layer has its own drain system connected to a water interceptor and monitoring system. The construction of the intermediate seals began in 1989. Such seals or equivalent measures, as well as the construction of inorganic barrier layers to protect the slopes and top surface, constitute a dependable multibarrier system. All contact of the waste in the landfill with the environment is blocked. This design ensures ecologically compatible and safe deposition of wastes for the long term [86].

The BASF landfill on the island of Flotzgrün in the Rhine has a double liner of plastic webs, insuring that all leachate is collected and delivered to treatment. The effectiveness of the liner

is continuously monitored, and leaks can be repaired [87].

5.4.4. Asbestos Disposal

Solvay Umweltchemie has devised a process for disposing of asbestos (the Solvas process). Asbestos with a particle size of ≤ 5 mm is reacted with hydrofluoric acid in a batch operation, yielding fluorides and hexafluorosilicates of the elements present in the asbestos-containing material. Crocidolite (blue asbestos) and white asbestos differ in reaction time. After filtration, the solids are neutralized with milk of lime and the filtrate is recycled. Neutralization yields a product consisting of CaF_2, oxides, and metal hydroxides of the elements present in the starting material, and silicate-containing compounds. This end product can be used as an additive in the manufacture of concrete blocks and as a flux [88–90].

5.5. Utilization of Product Wastes

5.5.1. Plastics Recycling

Plastics to be recycled after use must be collected in the purest possible form. The recyclable portion of the waste must be separated into classes of valuable substances or individual substances. The fractions that result can be

recycled for valuable constituents, recycled for feedstocks, or thermally utilized, depending on the type of plastic.

Recycling of Polypropylene. At its Knapsack site, Hoechst has erected a recycling plant for polypropylene with a capacity of 5000 t/a of PP recyclate (Fig. 17). Recycling makes it possible to start with pure PP fractions from used parts (such as those from automobiles) and modify them into "typeware." The material must be collected, ground, and sorted on a decentralized basis. The ground recycled parts are mixed with virgin PP powder, additives, and reinforcements, processed in an extruder, and thus converted to products that meet the required specifications [80].

Recycling of PVC Processing Wastes. A recycling plant for poly(vinyl chloride) wastes has been built at the Hoechst, Gendorf site. The principal feed is rigid PVC film trimmings from film processors. The plant has a capacity of 4000 t/a. The recycling line begins with grinding of the PVC wastes and removal of foreign substances such as paper, wood, and other types of plastic. At the same time, the PVC recyclate is washed and reground. After these steps, the PVC is subjected to final grinding, formulation, and conversion to new raw material for PVC film. In the same plant, this secondary feed is converted to PVC film for nonfood packaging and technical applications. The purpose of this prototype plant is to gather experience for future plants at other locations [80].

Recycling of Polyoxymethylene. The recycling techniques used up to now (regranulation and compounding) can damage polyoxymethylene. The consequences are separate specifications and application restrictions for recyclates. With a new process from Hoechst, these drawbacks can be avoided. The material recovered here is not the polymer itself but the monomer, chiefly trioxane, which is obtained by chemical degradation of POM wastes. The result of this recycling process is always new product. Only about 2 % of the POM recycling feed (consisting of stabilizers) becomes waste; this is combusted. The prerequisite for the process is that used plastic parts and processing residues be collected in pure form. A pilot plant is now in operation and a production unit is in the planning stage.

Recycling of PET Wastes. Hoechst Celanese has built a 70 000 t/a plant at Wilmington, Delaware, to recycle poly(ethylene terephthalate) wastes by methanolysis.

The glycolysis process is used in a recycling system (capacity 5000 t/a) for PET wastes at the Offenbach plant of Hoechst.

Recycling of Used Plastics. BASF is constructing a 15 000 t/a pilot plant for recycling of mixed, unwashed used plastics into feedstocks (Fig. 18).

The conversion of mixed plastics to petrochemical feedstocks takes place in a multistage melting and degradation process. In the first conversion stage, the used plastics are melted, and dehalogenated to protect downstream equipment from corrosion. Hydrogen chloride evolved in this stage is absorbed and fed to the hydrochloric acid plant. Gaseous organic products are compressed and can be utilized as feeds to a cracker.

In the next stages, the liquefied plastics are further degraded and fed to distillation towers. The distillates include naphtha, olefins, and aromatics, which are used as feedstocks in BASF's petrochemical plant. The high-boiling bottoms are converted to synthesis gas [91].

5.5.2. Refrigerant Recycling

In 1989, Hoechst decided that its output of perhalogenated chlorofluorocarbons (CFCs) should be phased out for environmental reasons and stopped by the end of 1994. The ozone-damaging CFCs are being replaced with R134a, whose contribution to the greenhouse effect is 90 % less than that of CFCs. The new product, like the earlier ones, is integrated into a two-stage recycling system.

Recycling of used CFC refrigerants was introduced in 1986 – 87. After collection by dealers, the essential processing steps are mechanical purification and distillation.

Refrigerant mixtures that cannot be separated by distillation, together with CFC still being delivered to Hoechst after production shutdown, are subjected to secondary recycling by a process that is patented worldwide. The refrigerants

are cracked in a thermal reactor, and hydrochloric and hydrofluoric acids are recovered from the reactor outlet gas (Fig. 19). These acids are used as feeds for other production processes [92].

5.5.3. Recycling of Used Packaging Materials

In a pilot project of the Verband der Chemi-schen Industrie, a facility for disposing of chemical drums was erected in the Hoechst Ruhrchemie plant. After pretreatment, drums with capacities of $\geq$120 L are cleaned, dried, and examined for damage and cleanliness. Clean drums are forwarded to recycling. Damaged drums larger than 120 (60) L as well as small containers (<120 or 60 L) are ground, washed, and dried. The materials, in the form of pure steel scrap or sorted plastic chips, are then available for recycling [93].

In 1991, BASF placed a central drum-cleaning plant in service. The next year, some 330 000 empty drums were cleaned in three automatic cleaning lines. The drums varied in size, material (plastic and steel), and design (open-head and tight-head). Two lines are run with water (with additives) and one with solvent [82].

5.5.4. Paint Recycling

Product development in water-based paints must consider how paint residues are to be recycled in the user's painting facilities. In certain paint systems, such as auto body paint booths, overspray is caught in circulating aqueous liquors and reconcentrated by ultrafiltration (see Fig. 20). Concentrate solutions are added to the appropriate paint formulations. In a special stove-drying paint system, the material recycling rate is ca. 95 %. The special membranes needed for the ultrafiltration step were developed by Hoechst subsidiaries Herberts and Hoechst Celanese Corporation, together with plant construction specialists.

5.6. Results of Waste Management

The results of waste management are characterized by two areas. The primary one relates to avoidance, reduction, and recycling of residues generated in production. This is achieved by means of production-integrated environmental protection (→ Production-Integrated Environmental Protection), leading chiefly to avoidance or reduction of waste.

The second area, waste disposal, exists because no chemical plant can operate without generating waste. Techniques used here include landfill disposal when appropriate, as well as waste combustion with energy recovery and modern flue-gas cleaning. Disposal is described in terms of the type, quantity, and disposal mode of the wastes. The following information on these processes has been provided by BASF, Bayer, and Hoechst:

BASF. The quantity of wastes combusted with energy recovery in 1983 was 94 000 t. This quantity rose steadily in later years, reaching 149 000 t in 1992. A decline to 143 000 t was recorded in 1993 (see Fig. 21).

Figure 21. Waste incineration at BASF, 1983 – 1993

Figure 22 shows the quantities of waste disposed of in the Flotzgrün landfill from 1983 to 1993. These wastes are classified as process wastes, wastewater treatment sludges, and building rubble and construction materials. The decrease in quantity since 1989 is attributed to recycling of building rubble and avoidance and recycling of process residues. Since 1992, all sludge from wastewater treatment has been combusted, so in future this source will contribute only ashes to the landfill. Other wastes deposited in the landfill in 1993 were 67 000 t of process wastes, compacted trash, trash from plant cleaning, and wastes from sludge combustion, together with 29 000 t of building rubble and construction materials [87].

Figure 22. Quantities of wastes deposited in the Flotzgrün landfill (BASF)

Bayer. The total amount of wastes generated in 1993 was 667 000 t. These quantities represent a reduction from the years 1981 – 1992. Figure 23 gives a breakdown of wastes with total quantities for the period from 1981 to 1993. The 7 % increase in waste produced between 1981 and 1988 was essentially due to a gain in production (nearly 16 % in the same period). Various practices introduced in production plants since 1988 have led to a reduction from 506 000 t to 339 000 t of production wastes in 1993 [94].

Figure 23. Waste quantities (Bayer)

Hoechst. The year 1993 saw a total waste production of 348 000 t, comprising 42 000 t of household-type waste, 173 000 t of sewage sludge, and 133 000 t of special and hazardous wastes. The last figure includes 44 000 t of contaminated building rubble and excavated soil. Figure 24 gives a breakdown by these same three waste categories for the period 1983 – 1993. The marked decline in total wastes generated and also in hazardous wastes can be attributed both to the shutdown of certain production operations and to production-integrated environmental protection [95].

The total waste quantity for 1993 (348 000 t) breaks down as follows:

Figure 24. Waste quantities (Hoechst)

Sewage sludge	55 %
Building rubble	16 %
Distillation residues	9 %
Solvents, solvent mixtures, mother liquors	7 %
Residential waste	5 %
Slag, ash	2.5 %
Plastics and polymer wastes	1.4 %
Diverse wastes	4.1 %

Waste disposal in 1993 breaks down as 89 000 t combusted and 259 000 t deposited in landfills.

6. Prevention of Waste

6.1. Introduction

Prevention of waste production can be achieved by two means: dispensing with production and consumption or technological waste prevention measures (see Fig. 25). Dispensing with production or consumption is the most dependable way to prevent environmental burdens due to human activity. Products that are not consumed need not be produced and thus cannot have an impact on the environment [96].

In contrast, the goal of technological waste prevention is to satisfy needs with minimal environmental impacts. Impacts result from consumption of resources and generation of wastes and emissions. Other prevention measures include cutting emissions to the atmosphere and water bodies, reducing the potential harm from emissions, increasing the service lives of products, and improving their recyclability. This task is of particular importance where all possibilities for dispensing with production and consumption have been exhausted, because products are required to at least meet basic human needs. Waste prevention is influenced by legislation but also by social and economic factors.

Technological waste prevention is broken down into primary and secondary waste prevention. Primary measures aim to reduce both the material stream and the material flow rate [97] by means of planning, development, and optimization of products. Here "products" refers to products for consumption and use, means of production, and infrastructures (buildings, transportation, and communications systems). The purpose of secondary waste prevention is to avoid disposal of products, production wastes, and waste materials by waste treatment or landfill deposition. Secondary waste prevention thus means recycling, the goal being to return the products to the use cycle at the lowest possible cost in material and energy terms. There are several forms of recycling: modifying or converting product while it is in use (re-use), recovering and reprocessing used products or waste materials after their useful life, and recycling production wastes and media back to the production process, with or without passing through a preparation process [98].

Integrated technical environmental protection cannot be analyzed in the same way as technical waste prevention (see Fig. 26) but does pursue the same goals. Integrated technical environmental protection is broken down according

Figure 25. Breakdown of waste prevention [96]

Figure 26. Structure and applications of integrated technical environmental protection [99]

to the system that is at the focus; i.e., product-integrated, production-integrated, and process-integrated environmental protection [99].

Product-integrated environmental protection [100] seeks to minimize use-specific environmental impacts over the entire career of the product (cradle to grave i.e. product line) [101]. This begins with extraction of resources from the earth's crust or biosphere and extends to the reintroduction of wastes and emissions into the natural environment. This approach is the most far-reaching under the different categories of integrated technical environmental protection and is the basis for unambiguous assessment of net reductions in environmental burdens.

The goal of production-integrated environmental protection [102] is to minimize the sum of environmental impacts within a company or a plant complex considered as a subregion of the company. Accordingly, the system boundaries are the boundaries of the company or plant complex. This approach has been developed by the chemical industry, in particular, as an instrument for economic and ecological optimization even where material streams are strongly cross-linked [103]. It can also handle multiple product lines in a company producing a range of prod-

ucts [101]. The procedure is also specified in European legislation (the "ecological audit" system) but cannot guarantee in every instance that a global optimum has been found for the products under consideration.

Process-integrated environmental protection [104] is a component of both product-integrated and production-integrated environmental protection and thus provides a link between these approaches. The objective is to minimize the sum of environmental burdens due to a process. This local optimum can contribute to the global "cradle-to-grave" optimum; that is, the process parameters that yield the global optimum may differ from those corresponding to the local optimum.

The technological basis for these integrated material- and process-oriented approaches comprises knowledge of materials, process and manufacturing engineering, and design engineering. Along with these technical aspects, instruments are needed to objectively assess the environmental burdens caused by the objects of study or anticipated for the future. The techniques of life cycle assessment, still being developed and standardized, will play a role here (see Chap. 4) [105].

Integrated technical environmental protection, like technical waste prevention measures, covers all technical actions and methods used to minimize environmental burdens due to products, services, plants, and processes. This is a holistic, systems-analysis approach that takes account of all interactions resulting from the individual technical measures. The overall aim is to ensure that products and services meet demands and carry out their functions, while raw material and energy consumption as well as environmental burdens are minimized.

6.2. Distinction between Primary and Secondary Waste Prevention

The distinction between primary and secondary waste prevention is equivalent to the distinction between legislatively mandated prevention and recycling [106]. An unambiguous distinction can only be derived by beginning the analysis with the process. As Figure 27 shows in simplified form, prevention is characterized by the fact that the masses m_0 inlet to the process are reduced by an amount m_p. In Figures 27 and 28, what is shown as a mass may actually be a sum of masses. If decreasing the original input m_0 entails the use of additional resources m_A, the actual prevention m_p is the difference between the sum of all actual inputs and the sum of all original inputs m_0. In this argument and those that follow, it is assumed that the mass m_Pr and the quality of the process product are the same in each case.

Figure 27. Simplified diagram of process-oriented waste prevention m_p

Figure 28. Simplified diagram of process-oriented waste abatement m_R (with recycling)

The recycling shown in Figure 28 leads to the replacement of some of the original input m_0 by secondary materials m_R generated in the recycling process. The mass input to the process is the same as the original input m_0 in Figure 27. When the system boundaries are expanded, no distinction is made between the re-

duction in mass m_p due to prevention and recycling; that is, if the entire production system is examined from an external viewpoint, primary and secondary waste prevention practices can cut the original amount of waste m'_W to the same value m_W. Apart from the closed- circuit aspect recycling involves at least one recycling process, which may be merely a transportation process. The input of matter and energy to this recycling process is not considered in the analysis of the process itself. In contrast to primary waste prevention, here it is not possible to state whether the net effect of recycling is a reduction in resource use and thus in environmental burdens [107].

Whether primary or secondary waste prevention is under consideration, process-oriented prevention must be distinguished from production- and product-oriented prevention. The avoidance of wastes and emissions from a given process can, but does not necessarily, lead to a reduction in the amount of wastes and emissions generated in the plant or throughout the product life cycle. The process analysis is the only certain way to distinguish primary from secondary waste prevention, or, in general, prevention from recycling.

6.3. Waste Prevention and Reduction of Environmental Burdens

The requirement to meet demand or carry out functions results in "profiles" of required product service properties. While a reduction in demand can be achieved by renunciation, technical waste prevention is based on meeting constant demand and thus unvarying requirement profiles for product properties. In other words, all further discussion relates to comparing products having the same benefit [108].

The environmental burdens produced by a product, directly or indirectly, throughout its life cycle from time t_0 when raw materials are extracted from the Earth's crust or biosphere up to t_∞ when wastes and emissions are reincorporated in the environment, are symbolized by $\mathrm{EB_{Pr}}$ in Equation (6.1). For each substance i, the ecologically weighted primary resource consumption M_{PR} (material and energy) and the ecologically weighted mass $\mathrm{M_{WE}}$ of wastes and emissions generated are summed over the life cycle. Ecological weighting takes into account the potential impacts due to the consumption of various resources and the generation of various wastes and emissions. As Equation (6.2) shows, the ecologically weighted mass M is the product of a weighting factor b and the mass m. The weighting factor b is formed similarly to the categories of the impact assessment of life cycle and takes account of, for example, the difference between a nearly environmentally neutral mining spoil and a far more relevant galvanic mud containing cyanide. Energy is treated similarly to mass, or the energy is converted to a corresponding mass of the primary energy resource [109].

Because any consumption of material and energy is equivalent to environmental burdens, there is no product that is absolutely environmentally friendly. For a given requirement profile the sum of the impacts on the environment (including those on humans) must be minimized by prevention measures. When a component or product can be made with more than one construction material or compound that meets the requirement profile, the material or compound that causes the least environmental burdens over the product life cycle should be chosen [99]. In contrast to Equation (6.1), where burdens are related to the product alone, the identification of the ecologically favored variant must allow for the service life $(t_e - t_n)$ or the frequency with which functions are carried out (Eq. 6.3). The sum of life cycle environmental burdens divided by the service life describes the material flow rate to be reduced [109]. The environmental burdens due to a product is not an absolute quantity, because the actual impacts cannot be quantified. For this reason, only the difference in use-specific environmental burdens (UEB) between two or more products can be determined (Eq. 6.4) in order to ascertain which product is ecologically more favorable and thus more environmentally benign. The attribute "environmentally friendly" is relative, not absolute.

$$\mathrm{EB_{Pr}} = \sum_{t_0}^{t_\infty} \sum_i (M_{\mathrm{PR}} + M_{\mathrm{WE}})_{\mathrm{t,i}} \tag{6.1}$$

$$M_i = b_i m_i \tag{6.2}$$

$$\mathrm{UEB_{Pr}} = \frac{\mathrm{EB_{Pr}}}{t_e - t_n} \tag{6.3}$$

$$\Delta \mathrm{UEB} = \left(\frac{\mathrm{EB_{Pr}}}{t_\mathrm{e} - t_\mathrm{n}}\right)_1 - \left(\frac{\mathrm{EB_{Pr}}}{t_\mathrm{e} - t_\mathrm{n}}\right)_2 \tag{6.4}$$

In Equations (6.1) – (6.4), EB denotes environmental burdens; M is the ecologically weighted mass; UEB is use-specific environmental burdens; b is the ecological weighting factor; m is mass; t_x is time (see Fig. 29); Pr refers to product, PR to primary resources, and WE to wastes and emissions.

Figure 29 illustrates how the environmental character of a product is determined as the ecologically weighted mass M for the product as a function of time over the life cycle [107]. For the sake of simplicity, the ecologically weighted masses of wastes and emissions (M_WE) are set equal to those of the secondary and primary resources ($M_\mathrm{SR}, M_\mathrm{PR}$). In reality they are generally different. In the time from t_0 to t_n, the finished product is manufactured in n process steps. From the primary resources PR and secondary resources SR input to each process step, the process product (shaded) and the wastes and emissions (white) are generated. During the product life, discrete quantities consumed are replaced by continuous consumption of media from primary resources. The wastes and emissions produced during the product life are not shown until the end of the service life t_e in this simplified plot. In the period from t_e to t_m, m process steps are carried out to produce secondary raw materials (SR). Primary resources are consumed in recycling and in subsequent waste processing and disposal. Waste processing includes air and water pollution control measures.

As Figure 29 shows, the life cycle of a product can be divided into four periods: manufacturing (M) ($t_n - t_0$), use (U) ($t_\mathrm{e} - t_n$), recycling (R) ($t_m - t_\mathrm{e}$), and waste treatment and disposal (D) ($t_\infty - t_\mathrm{m}$). Each segment of the life cycle contributes to the total environmental burdens $\mathrm{EB_{Pr}}$ (Eq. 6.5). For the product planner, the terms in Equation (6.6) are so-called ecological mortgages [99], which must be known in order to minimize the total environmental burdens.

$$\mathrm{EB_{Pr}} = \mathrm{EB_M} + \mathrm{EB_U} + \mathrm{EB_R} + \mathrm{EB_D} \tag{6.5}$$

$$\mathrm{EB_M} = \mathrm{EB_{M,PR}} + \mathrm{EB_{M,SR_1}} \tag{6.6}$$

The cumulative ecological burden for production is equal to the sum of environmental burdens due to primary and secondary resource consumption $\mathrm{SR_1}$ (Eq. 6.6). The production of secondary resources is analyzed as if secondary resources were generated not from recycled wastes but from primary resources. In other words, each environmental burden is determined from the ecologically weighted masses of primary resources balanced in i or j processes along with wastes and emissions (Eqs. 6.7 and 6.8). The cumulative ecological burden of recycling is the difference between the environmental burdens of the primary resources consumed and of the secondary resources $\mathrm{SR_2}$ formed (Eq. 6.9). For determining the resulting decreases in environmental burden, the secondary resources obtained by recycling are treated as if they were made from primary resources, not from wastes for recycling. In this way, the cumulative ecological burdens of recycling are the burdens due to recycling minus the burdens that would occur if the secondary resources were made from primary resources (Eq. 6.9) [110]. The cumulative ecological burdens of utilization ($\mathrm{EB_U}$) and waste disposal ($\mathrm{EB_D}$) are calculated analogously to Equation (6.7).

$$\mathrm{EB_{H,Pr}} = \sum_{t_0}^{t_n} \sum_i (M_\mathrm{PR} + M_\mathrm{WE})_{t,i} \tag{6.7}$$

$$\mathrm{EB_{M,SR}} = \sum_t \sum_j (M_\mathrm{PR} + M_\mathrm{WE})_{t,j} \tag{6.8}$$

$$\mathrm{EB_R} = \mathrm{EB_{R,PR}} - \mathrm{EB_{R,SR_2}} \tag{6.9}$$

Table 11 gives a breakdown of practices that can reduce environmental burdens, broken down by segment of the product life cycle and action areas.

The consumption of resources, the generation of wastes and emissions, and the pollution potential can be influenced throughout the life cycle. Measures taken to reduce use of resources are largely the same as those to decrease the amount of wastes produced. The most important life cycle segment for technical waste prevention, however, is planning and development as a component of production and manufacturing, since it is during this phase that the sum of the anticipated environmental burdens is determined.

The service life of a product is affected by planning and design, production, and use of the product. Recycling is a limiting case in that the service life is extended by the re-use of a used product but not by the recycling of a waste product. Recycling of a waste makes it possible to recover materials or other ingredients, and if these

Table 11. Possible ways to reduce environmental burdens over the life cycle of a product [96]

Segment of product life cycle	Ways to cut resource consumption	Ways to cut down wastes and emissions	Ways to reduce potential harm	Ways to increase service life	Ways to increase recyclability

Figure 29. Schematic depiction of ecologically weighted masses M over the life cycle of a product [107]
PR denotes primary resources, and SR secondary resources

are of suitable quality they can lower specific consumption of raw materials for making the product. The recyclability of a product generally can be predicted only in manufacturing, that is, during the design and development phases. An exception is the development of new recycling processes and the optimization of existing ones, which has a beneficial effect on recyclability [111].

6.4. Specific Actions to Reduce Environmental Burdens

The actions listed in Table 11 are specific steps, but by themselves they do not necessarily result in less environmental burdens over the product life cycle. Many of these measures interact with others and may even work against others. Global optimization in the sense of integrated technical environmental protection is necessary to determine how much each specific action is to be stressed.

6.4.1. Decreasing Resource Consumption

In Production. With regard to the consumption of raw materials per unit of end product, it is essential that the feedstocks and intermediates inlet to a process be transformed as completely as possible to the end product and that large fractions of these streams not be lost as residues or byproducts. The ratio of substances inlet to the process to substances present in the end product is called the yield. It is a measure of the utilization of substances entering the process. The higher the yield, the lower the consumption of raw materials and energy per unit of product discharged.

The energy efficiency is the ratio of energy utilized to the quantity of energy contained in primary energy resources. By increasing the energy efficiency, that is, lowering the energy consumption per unit of product, it is possible to decrease both the product burden and the use-specific environmental burdens (such as CO_2 emission). In this context, great importance attaches to improving the energy efficiency in elec-

tric power generation. In the steam or gas turbine used for power production, lengthening the blade cooling is one way to raise the inlet gas temperatures and thus increase the efficiency [112].

Processes must be controlled in such a way that feeds to the process are selectively transformed to the desired products with high efficiency and high yield, while inevitable wastes are suitable for recycling.

This presupposes a detailed knowledge of the process, the existence of a process model, and the availability of suitable instrumentation and control hardware including integrated process control systems. An example is the blast furnace, in which coke consumption has been lowered from 800 kg per tonne of pig iron to under 500 kg/t in the past 20 years as a result of these measure [113].

Batch processes always have an initial phase in which the process parameters are brought to their proper values, and a terminal phase in which the end product is discharged. Additional energy is required for both phases. If the material stream is large enough, batch operation can be changed over to continuous processing, in which the absence of the initial and final phases results in higher efficiencies and better yields.

Lightweight design not only cuts down the amount of resources consumed in making the product, but also reduces environmental burdens if the product has to be transported over long distances or where the product is itself the means of transportation. Lightweight design has a beneficial effect on energy consumption during use of the product.

The task of logistics is to ensure that goods reach the producer, or are delivered from the vendor to the customer, at the proper time and in the needed quantity. Logistics can contribute to waste abatement by route optimization, batch-size optimization, and full utilization of transportation capacity and selection of carrier [114].

Packagings consist of materials in the form of partial or complete coverings needed for the transportation, storage, or use of products as well as to carry product information. Thus superfluous packaging not required for a protective, informational, or transportation function should be dispensed with. Further packaging can be prevented by optimization of the filling quantity and optimization of packaging design, and in some cases by using returnable or multiple-use packagings.

Every process step involves the consumption of energy and materials, and thus the production of wastes and emissions. Whenever the number of operations required to make a given product can be reduced through process development and planning, this shortening of the process chain will result in smaller amounts of wastes and emissions [115].

In Use of the Product. One way product designers can reduce environmental burdens of consumer products is to prepare instructions that are easy to understand and easy to follow.

The most important practice in this area is the selection of products made by environmentally benign methods and featuring low consumption of energy, water, and/or other media. Objective information about the cumulative ecological burdens (mortgages) is a prerequisite for this practice (see Section 6.3).

Careful energy use means, for example, that only the amount of warm water actually needed is used or that heated rooms are only ventilated in a controlled manner.

Another significant potential for waste prevention is following the directions for the use of cleansers, detergents, care products, and other materials.

Good stocking practice can ensure that (in particular) foods, delicacies, and medications are not held past their sell-by dates and thus do not become wastes.

Proper maintenance is important for consumption of resources because it is the key to extending the life of plants, such as chemical industry facilities and machine tools, and of infrastructure, such as buildings and roads.

In Recycling. The opportunities for waste prevention in recycling are the same as in production or manufacturing. The frequently complex nature and rapidly changing composition of waste products, which are often mixed and/or contaminated, is a complicating factor. For this reason, process control in recycling is more difficult than in production processes where primary raw materials of well-defined composition are used. It is also more difficult to model recycling processes and additional instrumentation

and control measures are necessary to give high yields and quality.

In Waste Treatment. Achieving a high direct yield in waste treatment means minimizing the amount of energy and additives that must be put into the waste to make it suitable for landfilling. High energy efficiency is crucial, especially for thermal waste treatment.

As in recycling, the feeds to processing are mixtures with a broad spectrum of constituents, so that process control with low energy and material consumption is possible only with process modeling and appropriate instrumentation and control.

In Disposal. Like waste treatment, deposition in landfills is not a waste prevention measure. If waste volume is reduced, however, the capacity of existing landfills can be better utilized, so that landfill construction and operation entails less consumption of resources per unit of waste.

6.4.2. Reduction of Waste and Emission Quantities

The measures taken to reduce the production of wastes and emissions are largely the same as those used to cut resource consumption. The connection is formulated in the second "theorem" of waste sources [101]: Every resource extracted from the earth's crust or biosphere becomes waste and emissions.

One way to reduce the quantity of waste and emissions in manufacturing and production is to make sure that solid wastes, wastewater, and waste gases have high concentrations of pollutants. High concentrations of emitted substances reduce the absolute quantity of emission media and make it possible to recover valuable substances at low cost or to convert harmful substances to innocuous forms.

Similarly, low dissipation of valuable and harmful substances in the various media lowers the cost of recovery or separation.

After the product's useful life, proper disposal helps diminish wastes and emissions. If used products are sorted by type, recycling or waste processing will cost less than if they are left mixed.

6.4.3. Reduction of Pollution Potential

The use of low-pollutant feedstocks, auxiliaries, and media not only reduces the amount of new pollutants formed in the process but also keeps the quantity of emittable pollutants low. Low-pollution processes are those that have a high direct yield and high efficiency and do not contribute to the formation of new pollutants. The prerequisites for not producing new pollutants are a knowledge of the pollutant-forming mechanism (e.g., de novo synthesis of dioxins [116]), effective instrumentation and control, and design practices that, for example, shorten residence times or promote backmixing.

The use of renewable and degradable feedstocks is a way of cutting or eliminating waste. The use of renewable resources, if they are extracted in a "natural" and sustainable way, can both lower resource consumption and diminish the pollution potential of wastes and emissions.

The polluting potential of emissions can be reduced by separation and treatment of emissions from waste gases and wastewater that is, by measures of the additive environmental protection.

In use, the pollution potential can be reduced by selecting products made by low-pollution processes. Precondition is a comprehensive information.

Except for the use of renewable resources, the measures for lowering the pollution potential in recycling and waste processing are the same as those used in production and manufacturing.

The pollution potential in landfill disposal can be reduced if the substances are immobilized so that the landfill itself does not become a source of hazardous waste. Immobilization also diminishes the risk of pollutants escaping into the environment. This includes encapsulation and sealing of landfills not provided with adequate barriers.

6.4.4. Extending Product Service Life

To have service life, a product must perform the required functions and must afford the specified level of safety in use [117]. A product that does

not meet these requirements could fail prematurely, possibly causing an accident with environmental burdens.

Important manufacturing factors in the service life of a product are selection of materials, type of joints and fastenings, construction and geometry of the product, and nature and fabrication of the product itself [118]. This is a set of interdependent factors.

One way to lengthen service life is to use high-quality materials and composites with resistance to weathering, corrosion, wear, and biological attack. Generally, such materials have a higher cumulative ecological burden for manufacturing than do materials yielding a shorter product life. The selection of a high-quality material reduces environmental burdens only if the gain in service life is greater than the increased burdens due to manufacturing and recycling of the material (see Eq. 6.3).

The same holds for surface coatings (e.g., electroplating, enamel, paint) used to extend the life of a product. The added expense of the surface coating as well as the increased cost of recycling these composite materials must be considered.

The manufacturing technique can strongly affect the qualities of a material or structural element. Practices such as strain-hardening of metals can boost service life without increasing the amount of material used.

Appropriate use or consumption can increase service life during the product service period. If products are employed for purposes they were not intended for or under conditions not provided for in the directions, their service lives can be markedly curtailed.

Care and maintenance are important factors in extending service life during the product use phase.

At the recycling stage, lengthening the service life applies only to products intended for re-use for the same or another purpose. Appropriate practices include careful handling and, if applicable, mild cleaning and disassembly. For products that are not intended for multiple use but are still to be put to new use without any change of form, suitable processing and reconditioning processes must be devised.

6.4.5. Improvement of Recyclability

Measures to improve recyclability may conflict with the extension of service life (e.g., use of composite materials).

Because recyclability has to do with primary waste prevention, the only time when it can be controlled to reduce environmental burdens is at the design and development phases of manufacturing or production. Design for ease of disassembly and processing to improve recyclability [111], [119–121] may not be compatible with durable construction.

The fewest possible different materials, which in turn should belong to distinct classes of materials, should be used, so that they can be more reliably identified for sorting after product use and the cost of recycling in terms of resources is lowered and the yield is improved [122]. Substances whose structure does not survive the recycling process (e.g., fibers, plastics, and organic working materials) have only limited recyclability.

Where it is not expedient to separate substances for recycling, they should be chosen such that materials with well-defined properties are obtained on melting, which can be substituted for materials manufactured from primary feedstocks (waste material compatibility).

Recyclability is enhanced when few composite materials are employed. However, composites, including materials with surface coatings, are important for functional performance and increased service life.

Joints and fastenings should be made so that they can be taken apart easily and nondestructively after product use [123], [124].

A prerequisite for recycling is the unambiguous identification of materials to enable their sorting and recovery as materials with well-defined properties. In this way, separation and sorting can make a formerly unrecyclable product recyclable.

Complex products should be designed in modular fashion so that the only part that has to be removed is the nonfunctional one. Another aspect of design for recycling is to make service and maintenance of products easy and cheap.

6.5. Integrated Measures to Reduce Environmental Burdens

Global optimization of environmental protection by integrated practices throughout the life cycle or for a plant or plant complex depends on a knowledge of the capabilities and limitations of the actions discussed in Section 6.4. Within the boundaries of a given system, an integrated, systematic analysis can help to harmonize specific actions to reduce burdens, sometimes with a departure from the achievable minimum.

6.5.1. Product-Integrated Environmental Protection

Environmental burdens due to a product are not fixed; they can be crucially influenced in the product design and development process. The cumulative ecological burdens of the four life cycle segments depend on

1) The materials (substances) chosen
2) The processes and technology used
3) The design and manufacture of the product
4) Product-related actions taken over the full product life cycle

All product-related actions must be taken so that all product properties specified in the requirement profile are guaranteed over the intended lifespan. The avoidance of product defects is the basis for the first three elements of product-integrated environmental protection (listed above) and is presumed in the following discussion.

The selection of materials governs the nature of the resources to be extracted. This fact results indirectly (through availability and renewability) in part of the environmental burdens due to the material. The choice of resources also governs the quantity of wastes and emissions as well as their pollution potential. The service life and the recyclability of the product depend on the materials and the design but also on the technology employed. The useful life of a product has a decisive effect on the magnitude of use-specific environmental burdens (Eq. 6.3) of the product, while the recyclability determines the cumulative ecological burdens of recycling EB_R.

The process can be optimized to increase the yield or efficiency by means of process control technology. Prerequisites for this include a means for the continuous measurement of process parameters in liquid or gaseous media. For example, the partial pressure of oxygen is measured with specially developed materials such as doped and stabilized zirconium oxide [125]; newly devised metallic and ceramic protective tubes for temperature measurement in melts or off-gas streams are able to withstand a wide range of ambient conditions over the needed span of time. Shortening of the process chain also depends on the availability of suitable materials. One example is the production of sheet steel with an as- cast thickness of 1 – 3 mm [115] by the process of near-net-shape casting [126]. Until recently, this process was impracticable because there were no materials for delivering the melt, no materials for protective tubes, and no sensors for continuous measurement of temperature and oxygen potential. Thin-slab casting by the SMS process with upright chill mold for the casting of slabs 40 – 50 mm thick has been in industrial use since the late 1980s [127]. A special chill mold with a ceramic dip tube for melt delivery has been designed for this purpose.

The choice of cooling method for turbine blades (base, convection, film, or transpiration) depends on the material (iron-base alloy, ceramic), the design, and the fabrication method. The design of the turbine buckets governs not only blade cooling but also the maximum gas inlet temperature and thus the energy efficiency of the turbine [112]. Increasing the energy efficiency leads to a drop in specific CO_2 emissions.

Suitable technology is needed to make materials with specific qualities. This dependence begins with the fabrication of strain-hardened metals and is especially vital in the manufacture of metallic glasses (material with longer life span), which are made at a cooling rate of 10^5 to 10^7 K/s. Mirror glass is now made by the float process on a molten tin bath and requires no subsequent grinding and polishing (shortened process chain). To produce deep-drawing steel without costly final processing, the oxygen converter is essential. Powder-metallurgical techniques have major advantages over machining in that the piece can be made with nearly its final dimensions, so that there is far less machining and material wastage [128].

Apart from optimizing the reduction of environmental impacts by decreasing the cumulative

ecological burdens, it is necessary to determine which conditions in the requirement profile prevent the use of more environmentally compatible materials and whether the profile itself could be modified. Changes in the profile and possibly in design, if they do not appreciably bear on the satisfaction of demand, make it possible to use materials and processes with smaller cumulative ecological burdens.

6.5.2. Production-Integrated Environmental Protection

The goal of production-integrated environmental protection in the chemical industry is to achieve an optimum, from the process engineering standpoint, in the process or the manufacturing complex [103]. A manufacturing complex consists of several processes, which need not be directly linked. The term production-integrated environmental protection was developed in the chemical industry; today it is used in contrast to product-integrated environmental protection, which refers to optimization of environmental burdens reductions within a company or production plants. In production-integrated environmental protection, all chemical, physical, biological, and process and manufacturing engineering possibilities are utilized. The scope of the resulting process improvements can range from the optimization of single process components and extends up to modification of entire processes or of manufacturing complexes. It includes:

1) Primary waste prevention in the process.
2) Secondary waste prevention, that is, recycling of wastes in the manufacturing complex so that they can be used as feeds to other processes, or for energy production as the last and completing stage in the environmentally sound disposal of substances that cannot be reclaimed (waste for disposal, wastewater, and off-gas).

While additive environmental protection always leads to extra costs, the financial burden on the company can be reduced when production-integrated environmental protection is practiced.

Integration of two fundamentally different pyrometallurgical reactions in one vessel (QSL technology) made it possible to optimize the conventional process for lead refining, which consists of a traveling-grate sintering machine, in which the concentrate is roasted and sintered, and the blast furnace, in which the sinter is remelted under reducing conditions. In the cylindrical QSL reactor, autogenous roasting reaction melts of sulfur- and lead- containing feeds is followed by carbothermic reduction of the lead oxide bound in the slag. Along with the positive energy balance, emissions were cut relative to the conventional process: arsenic from 278 to 72 kg/a, lead from ca. 2000 to 150 kg/a, cadmium from 250 to 16 kg/a, and sulfur dioxide from 5230 to 89 t/a [129].

Improvements in chemical processes by using new synthesis routes and new combinations of process steps made it possible to develop low-waste processes in areas such as the high-tonnage production of polyethylene. In 1964, losses to the atmosphere were 9 %; to wastewater, 6.4 %; and to landfill, 1.3 %. With the new process, losses in 1986 were just 1.6 % in the boiler house and 0.4 % in combustion and landfill disposal of residues [130]. In the production of diphenyl bases, reduction with zinc has been replaced by a catalytic process. Solvents and sulfur acids are regenerated and recycled. So the generation of zinc oxide (formerly about 8000 t/a in Germany) is avoided [131], [132]. In polyester synthesis, process optimization in terms of plant and control systems made it possible to integrate recycle streams and purification steps into the plant so that virtually the only substances leaving the plant apart from the product are CO_2 and CO [130].

Gaseous, liquid, or solid wastes generated in a process, even under optimal operating conditions, can often be forwarded to several processes in the manufacturing complex. An example is the reclamation of residues by recycling directly to the process, for example return slag in the blast-furnace process [133], together with the use of such residues as feeds for other products.

An example of internal recycling in a metal surface-treatment operation is shown in Figure 30. By eliminating the introduction of foreign substances and electrolyte loss by entrainment, the number of rinse stages can be reduced, and the quantity of waste separated in the regenerator decreased. Reduced electrolyte entrainment also diminishes the volume flow rate $\dot{V}_R$

to the concentrator. This may even make it unnecessary to use a separate concentrator (e.g., an evaporator). The process liquor flow rate $\dot{V}_P$ is directly proportional to the inlet rate of foreign substances (e.g., organic contaminants in electrolytes, iron in hydrochloric acid pickling liquors, copper in peroxodisulfate etching liquors, oils in alkaline cleaning solutions). If this inlet rate of foreign substances can be reduced, the volume flow rate of process liquor $\dot{V}_P$ can be decreased, and this may permit the use of a smaller regenerator (ion exchanger, membrane electrolysis, ultrafiltration) [134]. Actions to reduce environmental burdens must be matched to the metal surface treatment process and may lead to dramatic changes in effluent relative to the open electrolytic system: Wastewater production cut by around 98 %; pollutant burden in wastewater lowered by 99 %; solid wastes, especially cell slimes, reduced by ca. 95 %. The concept illustrated has been used in a number of zero-wastewater electrolysis operations [135].

Changes in process and apparatus used for painting can increase the application efficiency and thus reduce the amount of paint sludge (see Section 8.4). Possibilities in spray painting include electrostatic spraying and airless spraying [136]. If the paint system is changed from solvent-based to water-based, solvent emissions can be markedly lowered. Recycling in the spray painting operation can lead to a 60 – 70 % reduction in paint-sludge wastes. The prerequisite for recycling paint in marketable quality is that overspray (paint which has missed the workpiece) be intercepted with no change in quality. A number of closed circuits are used. In a first cycle, paint is recovered in the paint booth by setting plates and belts behind the workpiece to catch part of the overspray and return it directly to the paint loop. A second cycle recovers paint not picked up in the first, which is discharged as paint sludge from off-gas cleaning. The sludge is dewatered, solvents are added, the liquor is sieved or centrifuged and depigmented, and paint is recovered. If the quality is to be maintained, unsuitable coagulants must not be introduced in the scrubbing step. The loop is closed by a third cycle in which the solvent escaping from the spray booth is recovered. This can be performed by adsorption on activated carbon followed by desorption of solvents, which can be recycled to the paint or used in cleaning the painting system [137], [138].

6.6. Determination of Environmental Burdens

The basis for optimizing environmental burdens is an objective determination of cumulative ecological burdens; that is, the sum of the environmental burdens resulting from the system under consideration. The instrument used is the "life-cycle assessment" method now being standardized (see Chap. 4) [105], [139]. This is a holistic approach to the objective and verifiable determination of environmental burdens caused by the object under study (product, company, plant, service, disposal route). The life- cycle assessment method is broken down into the following stages: goal definition and scope, inventory, impact assessment, evaluation, and improvement assessment (optional). Any life- cycle assessment must be presented in a comprehensible and verifiable way and must take account of the product's useful life. Accordingly, the goal definition must begin by stating the study purpose. Life-cycle assessment can be used for a variety of purposes: to optimize the object under consideration, to select among alternatives (products, materials, processes), or to develop environmentally benign products. The goal definition states, among other things, what object is being studied (product, company, service, or disposal route); what quantity will be used in the balance calculation (the functional unit); the time period of considered data; and the geographic and methodological boundaries of the systems compared.

In the inventory, material and energy inputs and outputs are balanced for each process within the system boundaries and aggregated according to the contributions of process products to the functional unit. The impact assessment aims to determine the potential impacts of the material and energy balances from the inventory in the most realistic way possible. The material and energy balance data are determined under impact categories such as resource scarcity, greenhouse effect, and damage to the ozone layer, and with equivalency factors such as years, global warming potential, and ozone depletion potential. At the current state of the art, the impact assessment can only be done for partial areas. The last part

Figure 30. Example of recycle streams eliminating wastewater generation in an electrolytic coating plant [134]
Φ is the degree of concentration; V_1 is the volume flow rate evaporated; V_2 is the rate of electrolyte entrainment; V_R the rate of rinse water; V_P the rate of process liquor; and c the concentration

of the life-cycle assessment, evaluation, is the least well developed at present [140]. Despite these limitations, if the inventory is carried out by a sound method and the impact assessment is taken as far as is now possible, the results can be a very good decision aid. Far-reaching and complex relationships can be reduced to a few easily surveyed data sets. Thus life-cycle assessment provides the only objective basis for reducing environmental burdens by optimization, selection, or development. Life-cycle assessment in practice is an instrument for measuring environmental burdens and reductions in burdens brought about by the system under examination. Practices of integrated technical environmental protection, like those of technical waste prevention, can now be consistently quantified with the help of life-cycle assessment.

7. Recycling of Waste

7.1. Introduction

7.1.1. General Aspects

The waste management includes recycling and various disposal operations. In waste recycling, the main purpose is to utilize the waste, not to eliminate its pollution potential. Disposal operations include physical, chemical, and thermal processing, as well as placement in landfills. According to the German Recycling Act (Kreislaufwirtschaftsgesetz) [141], wastes for recycling are thus distinguished from wastes for disposal.

Recycling is the measure of the secondary part of waste prevention (see Chapter 6.1) and includes not only reclamation but also the re-use of products or parts of products. Recycling means returning production wastes, post-consumption wastes, products, and parts of products to the production/consumption loop with no loss of quality. The term "recycling" applies only when the secondary raw material or secondary product generated can act as a substitute for a substance or a product of primary production. The term "upcycling" is used when an improvement in quality is achieved through recycling, and "downcycling" when the process is associated with a loss of quality.

In every form of recycling, the objectives are to preserve primary resources and landfill capacity, which is equivalent to reducing environmental burdens by diminishing the amount of wastes and emissions produced.

7.1.2. Forms of Recycling

A distinction is made between recycling of materials and recovery of energy content [142]. Recycling of materials is subdivided into various

forms of use and reclamation, which are shown schematically in Figure 31 along with consumption (use) and production. Each of the nine activities shown in the figure (numbered boxes) consumes primary resources and generates wastes for recycling (from boxes 3 – 7 to box 8) or for processing (from boxes 1 – 8 to box 9). The secondary resources (SR) generated in each activity become feeds for production. The term "waste" includes used products, used components, used assemblies, waste materials, and residues.

Recycling of Production Waste. Production wastes (Fig. 31, box 3) are all solid and liquid products that do not meet process objectives (product, coupled product), and are not wastewater. Production waste recycling is the return of production wastes to the same or a different production process. Examples of production wastes are sprues from injection molding, trimmings and stamping wastes, overspray from spray painting, and used lubricants. A characteristic of production waste recycling is the dissolution of the shape of solid wastes. This form of recycling is highly developed in some cases because wastes are collected in pure form and the knowledge required to process them is available. Often, production wastes can be processed in the same plant and returned to primary production.

Recycling during product use (reuse) (Fig. 31, box 4) means returning used products, parts, and assemblies to consumption without dissolution of their shape. Here "product" means goods for use and for consumption, equipment, and infrastructures (buildings and transportation and communications systems). Used products may be disassembled (nondestructively), cleaned, inspected, reconditioned or reworked, and reassembled. Examples include industrial robots, replacement auto engines, and photocopiers. Recycling during product use is characterized by the preservation of form and also by the use of manufacturing processes for reconditioning or reworking. In all other forms of recycling, wastes are processed in some way. The re-use of processed products for the same use, or the utilization of remanufactured products for a purpose different from the last means high-level recycling. As a rule, the consumption of primary resources is less than in other forms of recycling and the environmental burdens are therefore slighter.

Recycling of used products (Fig. 31, boxes 5 to 7) falls into three classes: product-specific recycling (box 5), material-specific recycling (box 6), and recycling of feedstocks (box 7). Which applies to a given used product depends on the degree of complexity, the construction, the composition, and the quantity. Recycling of used products typically involves breaking down the shape of the used product.

Product-specific recycling (Fig. 31, box 5) means returning the materials making up the used product as well as process media to production, following a procedure adapted to the product. Complex products containing many parts are processed by specially developed methods. Examples are automobiles, large household appliances, and computers. Still serviceable parts or assemblies are withdrawn in partial disassembly of the used product and forwarded to recycling during product use. Substances that can be sent to material-specific recycling and those that would interfere with further processing (copper, tin from steel bodywork) are also removed. In mechanical separation, the complete or partially disassembled used product is ground [143]. This is followed by sorting into fractions based on differences in physical properties (shape, density, particle size, electrical and magnetic properties, etc.) or possibly in chemical composition [144]. The various separation stages in product-specific recycling yield usable parts and assemblies, secondary materials for production, materials for material recycling and/or substances for recycling of feedstocks, and wastes for recycling or treatment. Components containing more than one substance may be passed on without further mechanical processing to thermal processing; for example, lead batteries may go to blast-furnace processing [145], or partially disassembled products such as compacted auto bodies may go to "metallurgical recycling" [146]. As a rule, product-specific recycling is accomplished by the method that entails the least consumption of primary resources compared to other forms of recycling of used products.

Material-specific recycling (Fig. 31, box 6) refers to obtaining well-defined materials from one or several used materials. In this context

Figure 31. Forms of recycling and their links to production, consumption, and waste disposal
PR denotes primary resources; SR, secondary raw materials

the notation of "material" is extended to include liquids and process media. These are fed into processes to make semifinished or finished products. Characteristic of material-specific recycling is that only physical operations are employed; there is no chemical transformation of the used substances. After sorting and washing, used metals and plastics are generally melted down to obtain well-defined materials. Because material-specific recycling does not involve chemical reactions, the inlet materials must be pure enough not to interfere with the production of a well-defined material (i.e., they must contain only small amounts of impurities, contaminants, and incompatible substances). Substances that are remelted together must be compatible in the sense that they can be made into a well-defined material, possibly after compensating for loss of alloying elements and auxiliaries. The prerequisite for this is collection in pure form. In the case of used plastics, material-specific recycling is referred to as mechanical recycling.

Recycling of feedstocks (Fig. 31, box 7) means the use of chemical and physical processes to return used substances to the production process. In contrast to material-specific recycling, here classes of substances together with foreign substances (deposits or impurities) can be used. The prerequisite, however, is that substances interfering with recycling can be separated by chemical reactions if physical separation is not possible. Typical of this form of recycling is that at least one separation step involves chemical reactions. The products of these processes that serve process objectives are fed to production processes and used in producing materials. In the case of used plastics, this form of recycling is also called chemical recycling.

Recycling of Residues. In residue recycling (Fig. 31, box 8) residues from a recycling processes (boxes 3 – 7) together with production residues are reclaimed. Such residues include, for example, slags, drosses, dusts, and sludges. Recycling of residues is characterized by a change in the nature of the substance in chemical reactions. The residues, after preliminary processing when needed, are fed into primary production processes for two reasons: These processes are suitable for the recovery of valuable substances, and no recycling technology is available for certain wastes. Residues from production forwarded to residue recycling differ from recycling process residues in being pure (sorted) and free of foreign substances.

Recycling for Energy Recovery. According to the German Recycling Act, wastes can be recycled as materials or used to produce energy. The method selected will be the one that causes the slighter environmental burdens. The term recovery of energy content is used when wastes are used as a replacement fuel and the principal aim is to utilize the heating value, not to reduce the pollution potential [141]. Thermal processing to dispose of wastes is not the same as recycling for energy recovery. The Recycling Act permits energy recovery only when a particular waste, unmixed with other substances, meets the following tests:

1) The heating value of the waste (except for wastes from renewable resources) is at least 11 000 kJ/kg
2) A furnace efficiency of at least 75 % is attained
3) The heat produced is utilized
4) Wastes generated by the process can be placed in landfills with the minimum possible further treatment

7.1.3. Prerequisites for and Limitations of Recycling

Recycling as materials can be said to occur only if it is possible to substitute secondary resources for primary resources in production. Recycling for energy recovery must replace primary energy resources. While there are quality changes in upcycling and downcycling, these two special forms of recycling must meet the same criteria as recycling of materials.

The basic precondition for recycling is collection of production wastes, used products, and residues. The form of collection and the logistics involved in delivering the materials to the recycling plants have significant effects on the consumption of primary resources and thus on the environmental burdens, the costs, and the economics and quality of the secondary products or secondary materials. Primary resources can be replaced by secondary materials only if the product quality is maintained. Together with a lack of universal acceptance for products made from secondary materials, other constraints arise from issues of product liability, technical codes, legal restrictions, unrealistic demands from consumers, and excessively strict requirement profiles written into specifications. The basis for overcoming these hindrances is consistent, guaranteed quality of recycled products [147].

In addition, it is essential to make certain that recycling actually does relieve environmental burdens in comparison with the use of primary resources and that recycling is economically feasible. These prerequisites can be met only if the following conditions hold:

1) Adequate recycling logistics (collection and transportation)
2) Sufficient quantity of suitable waste (production waste, used products, waste substances, and residues) to keep the recycling facility utilized over its depreciation life

3) Adequate demand for secondary products and secondary raw materials over the depreciation period
4) Availability of sorted wastes without interfering deposits or impurities
5) Recyclability of the used products (design for recycling, recycling compatible materials, etc.)
6) Dependable means of disposal (treatment and/or landfill deposition) of wastes generated in recycling
7) Availability of suitable recycling technology

The limitations of recycling can be classed as ecological, economic, and technical. To decide whether recycling is ecologically or economically desirable, it is compared with disposal of the waste in question. Recycling is economically preferable to disposal if the sum of the proceeds from secondary feedstocks and non-recycling disposal costs is greater than the cost of recycling (Eq. 7.1). The point at which proceeds equals the difference in recycling and disposal costs is the breakeven point [148].

$$P_{\mathrm{SR}} + C_{\mathrm{D}} > C_{\mathrm{R}} \rightarrow P_{\mathrm{SR}} > C_{\mathrm{R}} - C_{\mathrm{D}} \tag{7.1}$$

$$M_{\mathrm{SR}} > \mathrm{EB_R} - \mathrm{EB_D} \tag{7.2}$$

where C stands for cost, P for proceeds, M for the ecologically weighted mass, EB for environmental burdens, D for disposal, SR for secondary resources, and R for recycling.

The ecological limit of recycling occurs at the ecological breakeven point (ebep) [149]. Recycling is preferable to disposal for a given waste only when the decrease in environmental burden, represented in Equation (7.2) by the ecologically weighted mass [149] of the secondary raw material, is greater than the difference in environmental burdens between recycling and disposal (Eq. 7.2). The environmental burdens in each case are the sum of all resources used and all wastes and emissions generated within the system under analysis. Environmental burdens are determined by the life cycle assessment method. The secondary raw material produced by recycling is not in itself a quantifiable reduction in environmental burdens. Because this secondary resources replaces a substance that would otherwise have to be made from primary resources, the decrease in environmental burdens is equal to the burdens that would arise in the production of this secondary feed from primary resources. These theoretical burdens make it possible to quantify the decrease in burdens as M_{SR} in Equation (7.2). The ecological breakeven point occurs when the left- and right-hand sides of this equation are equal. If the ecological result of recycling is below the breakeven point in this comparative analysis, the contemplated form of disposal is preferable to recycling from an ecological standpoint.

Technical limitations on recycling arise from the fact that logistical systems and recycling methods are not available for some wastes and the attainable quality of secondary feeds or products may not be sufficiently high. Recycling for recovery of materials also faces a technical limitation when the recycling technology damages the substances (e.g., paper and plastics).

Figure 32. Three options for the handling of a waste
The utilities of the three systems are made equal by adding "complementary goods" CP_x to the secondary raw materials SR_y

7.1.4. Selection of Disposal Route

Figure 32 shows alternative routes for recycling as materials and waste treatment (waste processing and landfill disposal). A third option is energy recycling. For a given waste, the option chosen must be technically feasible and economically reasonable and cause the smallest total environmental burdens.

The precondition of recycling is technical capability. The economic aspect is based on a pure economic analysis. The ecological considerations involved in this choice are more complex, and it is these that are discussed in what follows.

The life cycle assessment technique (see Chap. 4) is used to determine environmental burdens for each pathway. In this partial assessment for the post-consumer sector, it is not possible to determine a functional unit. The waste at the beginning of each route is identical in quality and quantity; the quality and quantity of the secondary resources are a function of the particular recycling or disposal option. The benefit of a commodity, in this case a secondary resource, comprises objective and subjective factors, i.e., measurable and unmeasurable quantities. As a result, each pathway generates secondary resources differing in benefit, and this benefit is generally not measurable. If the options are nevertheless to be compared, the benefits of the systems must be made equal. The way of doing this is to render the goods produced in each system identical in quality and quantity. This is done, as shown in Figure 32, by placing complementary products (CP) in the "shoppingbasket" of each system. When two options are being compared, the complementary products added to one correspond, in quality and quantity, to the secondary resources produced in the other. Because the complementary goods generated from primary resources correspond in quality and quantity to the secondary resources, the baskets are equal in benefits and the systems can be compared (see Eq. 7.3) [150].

$$\mathrm{SR}_x = \mathrm{CP}_x \tag{7.3}$$

$$\mathrm{EB}_\mathrm{A}^\mathrm{S} + \mathrm{EB}_\mathrm{B}^\mathrm{P} \Leftrightarrow \mathrm{EB}_\mathrm{A}^\mathrm{P} + \mathrm{EB}_\mathrm{B}^\mathrm{S} \tag{7.4}$$

where SR denotes secondary resources; CP stands for complementary products; EB are environmental burdens, A and B are goods; and P and S refer to goods produced from primary and secondary resources respectively.

It is not the benefits that are compared; these are equal. The comparison is between the environmental burdens of the two equal-benefit systems (Eq. 7.4). The option with the smaller environmental burdens is preferable from the ecological standpoint for the given waste.

7.1.5. Recycling Rates

Recycling rates are calculated in different ways and may therefore be reported differently for a given situation. The recycling rate should reflect what fraction of the material in question (from production process 1) is contained, after use and recycling, in the resulting products from process 2. The relationship is described by equation (7.5) for one substance; Figure 33 illustrates the operations and the notation. The equation holds for materials or substances derived from used (waste) products and residues.

Figure 33. Block diagram used in deriving equations for the recycling rate

The equation does not apply to the recycling of production waste but can be extended to this case; it is therefore usable for both closed-loop and open-loop recycling. Equation (7.5), and also Equations (7.6) – (7.8) derived therefrom, presuppose that the masses under consideration have been adjusted for changes in stock as well as exports and imports. If the losses in the second production process (mass flow rate $m_{2\mathrm{D}}$) are zero, Equation (7.5) becomes Equation (7.6). The recycling rate is the ratio of the

Figure 34. Quantitative breakdown of wastes in Western Europe

mass flow m_{12} into the second process to the rate m_1 into products from the first process. These two ways of determining the recycling rate are seldom used because it is difficult to relate the argument to m_1, especially when long spans of time intervene between the first and second production processes, as is the case with durable goods.

$$R_{\mathrm{C}} = \frac{m_{12}}{m_{12} + m_{\mathrm{p2}}} \cdot \frac{m_2}{m_1} \tag{7.5}$$

If $m_{2\mathrm{D}} = 0$, then $m_2 = m_{12} + m_{\mathrm{p2}}$ and

$$R'_{\mathrm{C}} = \frac{m_{12}}{m_1} \tag{7.6}$$

If $m_1 = m_2$,

$$R_1 = \frac{m_{12}}{m_{12} + m_{\mathrm{p2}}} \tag{7.7}$$

If $m_{2\mathrm{D}} = 0$ and $m_1 = m_2$,

$$R_2 = \frac{m_{12}}{m_2} \tag{7.8}$$

where R_{C} is the "correct" recycling rate (the other R being the recycling rate derived from this), and m_{x} are the stream volumes as shown in Figure 33.

If m_1 is set equal to m_2, it is not necessary to consider two time intervals, and Equation (7.5) becomes Equation (7.7). This form of the recycling rate is frequently chosen; the error is larger, the more m_1 and m_2 differ. If the assumptions used to derive Equations (7.6) and (7.7) are applied together, Equation (7.5) takes the form of Equation (7.8). Here the recycling rate is the simple ratio between the mass flow rate m_{12} inlet with secondary resources to the mass flow rate m_2 discharged. This figure is also often quoted as the recycling rate. Of all the formulas listed, it has the largest potential error.

For a given situation, the recycling rate can vary widely depending on what relation is selected. In neither case, however, does it say anything about whether recycling is ecologically desirable in the given case. Firstly, the analysis is generally based on averaging all recycling results for a given substance within a time interval; secondly, no information is given here about the environmental burdens due to recycling or the reductions in burdens that result.

7.2. Plastics

7.2.1. Introduction

In all densely populated areas of the industrialized countries, recent years have seen major

bottlenecks develop in waste disposal, because of exhaustion of landfill capacity as well as a lack of acceptance of waste combustion plants. Legislators in some of the hardest-hit countries have been driven to impose harsh restrictions. Some of the new provisions discriminate against plastics in general or certain types of plastics.

Examples are found in acts and regulations issued in Germany, which are based on two key principles:

1) The polluter pays principle, which transfers responsibility from communities to parties generating waste or marketing products that will become wastes. Examples are the Packaging Regulation (Verpackungsverordnung) of 1990 and the Regulation on the Disposal of Used Autos (Verordnung über die Entsorgung von Altautos).
2) The recycling principle, which is embodied in the new Federal Waste Act (Abfallgesetz) and states that reuse has priority over other disposal practices for all products.

The Packaging Regulation, already in force in Germany, not only confuses the total waste streams for paper and glass and discriminates against plastics as a packaging material, but also imposes vastly increased prices for classical disposal routes, in particular landfill disposal. Costs for plastic wastes rated as nontoxic are currently at least 260 €/t – 100 times more expensive than 10 years ago.

A provision that merits especially critical examination is the ban on incineration and thermal utilization of waste plastics packaging. No such provision can be found in regulations now in effect or contemplated for the rest of Europe, and even in Germany this act may be subject to revision [151]. The second plastics-related problem with the German regulation is that its deadlines are too short and its quotas too high. These have already brought *Duales System Deutschland*, a new concept set up to collect household packaging wastes, to the brink of ruin.

Household waste and its disposal is the most serious problem in the case of plastics, because this type of waste is highly soiled and almost inseparably mixed with other plastics, paper, and metals. Figure 34 shows a quantitative breakdown of wastes for the EU countries. Plastics represent only 7 wt % of residential waste and thus represent a minor problem in the total waste streams, 70 % of which currently is destined for landfills. This is so in spite of the fact that the volume fraction of plastics in a landfill may be a factor of 2 – 3 greater than the weight fraction.

Current widespread public aversion to the chemical industry, and hence to plastics, is hindering approval of specialized disposal methods. Plastics recycling has therefore been exemplified by mechanical recycling – long regarded by experts as suitable for only a small fraction of plastics wastes – as is typical for competing materials such as metals and glass.

7.2.2. Mechanical Recycling

7.2.2.1. Chemical Basis for Plastics Recycling

At a certain elevated temperature, determined by the polymer chain structure and chain length, thermoplastics soften and melt because the molecules can move independently of one another. This movement intensifies as the temperature rises. In this state, the molecular structure can be thought of as a "felt" of threads, with individual molecules forming coils whose outer ends are entangled with one another (Fig. 35 A).

Polymers do not exhibit a vapor state because the macromolecules are cleaved to hydrocarbon fragments before they can vaporize.

Polymer molecules can also be degraded at low temperatures, for example as a result of severe mechanical stress, the action of moisture and chemicals, or radiation, such as ultraviolet rays. This kind of damage, known as aging, chiefly affects molecular chains extending from the outside of the coils; these are the portions of the molecules that formed the entanglements (Fig. 35 B). A degraded coil is thus linked to its neighbors by only a few entanglements, so that the melt is less viscous. This is often an advantage in processing, but it also reduces the toughness of the solid plastic, leading to impact brittleness.

Polymers with different molecular structures repel one another on solidifaction. Thus a melt of mixed plastics segregates on cooling, forming phases that no longer cohere with one another (Fig. 35 C). The second polymer forms a separate phase, which encloses the coil of the first

Figure 35. Changes in the physical structure of thermoplastics

resin like a shell, forming an interface that interferes with the entanglement of like molecules. Components made of such polymer blends have adequate mechanical properties only if the second phase is uniformly distributed and very finely dispersed in the first, or if chemical additives can be used to keep the unlike molecules from repelling one another and allow them to become entangled.

In mixtures of polyethylene with up to 10 % polypropylene (or vice versa), such fine dispersion can be achieved with compounding screws, and good properties can be obtained. When the phases are too large, they lead to surface structure variations, apparent as optical defects.

7.2.2.2. Pure Wastes

Broad experience has been gained with recycling pure thermoplastics. All manufacturing plants have processed pure wastes by grinding and incorporating them into new products since the beginning of thermoplastics production. A typical modern processing machine that can incorporate pure, clean recycled material into virgin stock is an injection-molding machine in which a bypass extruder melts recycled plastic granules and meters the melt into virgin stock through a fine filter. Up to 30 vol % of recycled plastic can be introduced.

In the automobile industry, the removal of plastic components from used bodywork and their remelting to make new moldings has already become standard practice [152–154]. Automakers now accept products made from recycled plastics or containing a fraction of recycled plastic, provided the recycled granules meet certain specifications of uniformity and quality, certified by neutral testing [155].

Figure 36. Polypropylene bumpers (BASF)

The requirement to use a higher proportion of recyclable plastic components in consumer products, including automobiles, has already led to redesign. The variety of materials has been narrowed, and composite parts have been replaced by assemblies made of a single material. As a result, simple disassembly yields large amounts of pure material for recycling. A typ-

ical example of a good design of this type is the bumper assembly shown in Figure 36, in which all the components are made of polypropylene. The shock-absorbing part is made from a newly developed polypropylene foamed-pellet material [156], and the supporting bracket from polypropylene with long-fiber glass reinforcement. This construction makes it possible to remove 30 % of the plastics in a modern automobile in about 30 min [157].

7.2.2.3. Mixed and Soiled Plastics Wastes

Products from Mixed and Contaminated Plastics Wastes. There are several processes by which useful objects, such as planks and posts for park benches or brick substitutes, can be produced from mixed and unpurified resin wastes. Figure 37 shows a plant consisting of pelletizing and compounding units as well as plasticizing and compression-molding machines. The market for such articles is limited, and they are difficult to sell because the items they replace are cheap. Up to now, only subsidized products have survived on the market.

Separation of Mixed Plastics Wastes. To make competitive products of adequate quality from contaminated and mixed plastics wastes, separation into pure fractions is necessary. The steps required are as follows:

1) Grinding to pellets ca. 1 mm in diameter (an expensive operation)
2) Washing
3) Separation of particles by density (at most two different plastics with ca. 99 % purity per operation, so economical separation depends on minimizing the number of plastics in the mixture)
4) Drying

Experience in recent years has shown that this method of processing into new plastics does not offer competitive prices and thus can be considered only if subsidized.

Dissolution. Thermoplastics can be dissolved in certain solvents. This technique used to be quite important in the production of films and fibers and is still used for some lacquers (e.g., nail polish) and adhesives for hobbyists. On environmental grounds, the technology is virtually extinct in industry. The solvents, most of which are toxic, could not be completely recovered from the products, and the equipment could not be sealed tightly enough to prevent them from escaping into the surroundings.

The dissolution of thermoplastics is based on the chemical affinity of some liquid hydrocarbons for certain resin molecules. When a suitable solvent comes in contact with a plastic, it diffuses into the material and penetrates the tangle of molecules. When enough solvent has been absorbed to fill the molecular coils, the plastic begins to swell. If more solvent is added, the molecules separate from one another to form a solution. This process is reversible, and if the solvent is evaporated, the polymer remains behind as a film.

If a selective solvent is used, only polymer molecules of one certain type are dissolved. It is even possible to treat mixtures such as thermoplastics in household waste with a single highly selective solvent, and by varying the temperature and pressure to dissolve several pure plastics one after another [178]. Dissolution is then a physicochemical method for recovering pure plastics from mixed plastics wastes. An example of the selective dissolution of mixed plastics wastes with THF follows:

First cut:	room temperature	
	Poly(vinyl chloride)	> 99 %
	Polystyrene	> 99 %
Second cut:	70 °C	
	low-density polyethylene	> 99 %
Third cut:	160 °C	
	polypropylene	> 99 %
	high-density polyethylene	> 99 %
Fourth cut:	190 °C	
	poly(ethylene terephthalate)	> 99 %

The dissolved fractions can be purified by filtration before the solvents are removed by evaporation.

A pilot plant with a capacity of 50 kg/h was started up in the United States. Costs for the recovered pellets are estimated at ca. 0.4 €/kg for a 25 000 t/a plant. Because of strict environmental regulations, this process would be far more expensive in Europe and therefore would be limited to special cases.

7.2.2.4. Fiber Composites and Other Thermosets

Thermosets are cross-linked resins that cannot be melted because the process that created the cross-links is irreversible. Typical products are auto body parts made from sheet molding compounds (SMC) which contain only 30 vol % of the resin together with 60 vol % fillers and reinforcing fibers. Pure wastes of this material can be pulverized in a hammer mill [158] and the powdered resin and fibers recovered, and used as additives for new moldings. The majority of the glass fibers are obtained in usable lengths, and are almost completely separated from the binding resin, which is reduced to dust. The mill discharge can easily be separated into three or more fractions:

1) Powder consisting of resin and short glass fibers (<0.5 mm)
2) Fiber bundles with fiber lengths up to ca. 5 mm
3) Fiber bundles with lengths > 5 mm

The powder fraction is added to a new batch of resin in amounts of up to 20 %, replacing mineral powder filler. Most of the middle fraction can also be incorporated in new resin. The long-fiber fraction cannot be utilized in SMC because it would interfere with the spreading of the resin paste. But it can be used as reinforcement in short-fiber glass-reinforced thermoplastics or in molding compounds. The prerequisite is an adequate and dependable supply of pure recycled material of uniform quality.

7.2.2.5. Outlook for Mixed Wastes in Blends

Modern blending technology could also be applied to mixed plastics wastes [159]. However, the blend must be completely homogeneous and must not change over a long time span. The wide variations in properties that would result from any fluctuation mean that blends are limited to a few applications. Because this technology will be restricted to special cases, it is not discussed further here; the reader is referred to [159].

7.2.3. Degradation to Molecular Constituents

In theory, the relative ease of degrading polymers into their molecular constituents should allow their disposal, or the monomers of low molecular mass polymers obtained by degradation could be repolymerized. Both methods are under investigation.

7.2.3.1. Biodegradable Plastics

Physically, polymers with their long-chain molecules represent a higher state of ordering than the small monomer building blocks. They therefore break down under the environmental conditions. Modern plastics, however, are designed for long service life and contain chemical stabilizers, so that they retain their useful properties over a long period under normal conditions.

The degradation process can be accelerated simply by omitting the stabilizers or even by

adding initiators that increase the rate of degradation. This approach leads to plastics that degrade spontaneously, also called biodegradable plastics.

In the ideal case the degraded plastics would break down into nontoxic, naturally occurring molecules. Such materials are commercially available. They disintegrate into readily degradable molecules derived from natural products, such as starches. Plastics of this kind are already in use on a limited scale. An example is Biopol, a biodegradable plastic obtained from bacterial cultures, used for hair spray containers. These substances are several times more costly than the plastics currently used for packaging.

7.2.3.2. Chemical Recycling

In chemical feedstock recycling, the polymer chain molecules are broken down into smaller hydrocarbon molecules, which are fed to polymerization reactions. The process leads from polymers to monomers or, finally, back to oil.

With regard to the energy balance (Fig. 38) as well as costs, these processes fall between pure remelting and combustion.

There are two methods by which polymer molecules are cracked:

1) Chemical degradation by hydrolysis or hydrogenation
2) Thermal degradation (Fig. 39), where the molecules are disintegrated by heat alone (as in pyrolysis) or with addition of oxygen, which lowers the process temperature.

Catalysts are necessary or at least advantageous in each case.

As Figure 39 shows, this depolymerization or degradation leads directly to the monomer in some cases, and to a mixture of liquid or gaseous hydrocarbons in others. These low molecular mass substances can be readily separated and purified by standard methods and used as new feedstocks.

7.2.3.2.1. Chemical Degradation

Hydrolysis, Methanolysis, and Glycolysis. As early as 1981, hydrolysis was one of the topics investigated in the VKE research project [160], [161]. This process makes use of the fact that polycondensation, the reaction used in making polyamides and polyesters, is an equilibrium reaction in which at elevated temperatures the presence or absence of water governs whether the chains grow or are degraded. If water is added to a polycondensate at a high temperature, the compound decomposes to its monomers. A system for carrying this process, comprising a twin-screw extruder in which water or steam is injected into the polymer melt, is illustrated in Figure 40.

In the related process of methanolysis, a polymer such as poly(ethylene terephthalate), PET, is melted and mixed with methanol; depolymerization takes place between 160 and 240 °C. Feedstock recovery in the process is 99 %.

In the glycolysis process, PET is treated with an excess of glycol over catalysts and broken down into larger molecular fragments.

The alcoholysis of PET, polyurethane, and polyamide wastes from automaking has undergone a research renaissance [162]. An interesting potential application is the steam hydrolysis of foams from old auto seats. In the same way, the important bottle material PET can be made into new PET that is suitable for the same use.

This process can be performed on all polymers that contain carbonyl groups, although the monomers are not recovered in all cases. For example, diisocyanates are not obtained from polyurethanes.

Hydrogenation. When liquefied coal or liquid coal derivatives such as hydrocarbons are treated with hydrogen at 450 – 500 °C and 200 – 300 bar, the product is a mixture of a small amount of gas, much naphtha and oil, and some bitumen. This hydrogenation process (Fig. 41) was used to make high-quality fuels from coal in Germany during World War II. It yields a higher proportion of valuable liquid hydrocarbons (listed in Fig. 42) than does pyrolysis, although the plant is more expensive to build and operate. Of all the degradation processes, it is energetically the most favorable [163] because valuable oils and naphtha are generated preferentially. One of the few plants in the world using this liquid-phase hydrogenation process is the Kohle-Öl-Anlage facility at Bottrop, which takes in 25 t/h of heavy oil from the nearby

Figure 38. Energy balances for several processes involving polyolefins, with the enthalpy shown for comparison

VEBA refinery and produces naphtha and synthetic crude oil that are returned to the refinery as feedstocks.

In 1992 this plant processed 2000 t of mixed plastics packaging wastes. The wastes were ground to < 1 mm, mixed with the heavy oil (up to 7 %), and processed with it. A particularly high quality syncrude was obtained.

After expansion of the plant and improvement in the preparation of plastics wastes, capacity for these wastes will grow to 40 000 t/a after summer 1993, and subsequently to 200 000 t/a. VEBA is contemplating the erection of four more plants in Germany; these will have larger throughputs than the pilot plant now on stream, so that a capacity of over 10^6 t/a may be available by the year 2000.

7.2.3.2.2. Thermal Degradation

Pyrolysis. Bonds in polymer molecules are broken at elevated temperature, the chain strength depending on the nature of the covalent bonds:

If air is excluded, chain cleavage begins at ca. 200 °C, and the molecular mass of the products decreases as the temperature rises: initially polymers, then hydrocarbons are obtained. This process is called pyrolysis [164].

Figure 39. Options for depolymerization and degradation of resins

Figure 40. System for depolymerization by hydrolysis (Bayer) under the action of steam, shearing, and high temperature and pressure (250 – 300 °C, 25 bar, 5 – 20 min residence time)

Most of the plants now in operation are pilot plants [165] not specially designed for plastics but able to handle general refuse [166]. Because the goal is to obtain pyrolysis gas for use as heating fuel, these systems are operated above 1000 °C, so that the macromolecules are completely broken down.

If higher hydrocarbons and useful oils are to be made from plastics wastes, the plant must operate at ca. 700 °C (Fig. 43). PVC is separated from the feed, since chlorine poisons the product oils and would necessitate an expensive downstream dechlorination step. Unfortunately, pyrolysis yields large amounts of gaseous hydrocarbons, which can only be used for process

Figure 42. Products obtained by liquid-phase hydrogenation (KAB)

heating unless the plant is part of an integrated manufacturing complex.

This process is thought to be promising for elastomer wastes (such as auto tires) because they can be inlet to the process without grinding.

Degradative Extrusion. In degradative extrusion [167] a mixture of diverse polymers is treated at high temperature and under shearing, with reactive gases such as oxygen (air) and hydrogen (water), and in some cases catalytic additives such as metal oxides. The plastics are rapidly degraded to a homogeneous melt of low molecular mass polymers. Figure 44 shows two plants based on standard extruders. The first stage in the process removes chlorine, which originates chiefly from PVC in mixed plastics wastes. By suitable screw design, this is achieved

solely by heat and shear for PVC contents of up to 100 %; the chlorine content of the end product is < 0.3 %.

Figure 43. Fluidized-bed pyrolysis plant (after KAMINSKY) a) HCl absorption; b) HCl separation; c) Pyrolysis; d) Incineration

The mixture can also contain up to 40 % elastomers and thermosets, which are pulverized in specially designed screws. At ca. 400 °C, the discharge from the extruder is an oily liquid, which at room temperature solidifies to a brittle wax, suitable for various uses (Fig. 45). The oil, for example, can be fed directly to a hydrogenation reactor, a synthesis gas unit, or a blast furnace (forming a reaction gas for metallurgical processes; see Fig. 46). The extruder product can also be made into a conveyable powder or pellets. It would thus be possible to convert the wastes into an appropriate homogeneous form at the point of waste generation using a single extruder. The powder, pelletized material, or melt can then be forwarded to the actual processing plant (e.g., pyrolysis or hydrogenation) or to a refinery where it is mixed with crude oil or heavy oil fractions for processing in a cracker or hydrogenator. The material can also be stored indefinitely without danger. If the heavy oil is to be used as a refinery feedstock, the chlorine content must be < 20 ppm; work is now under way to attain this level.

A degradative extrusion plant for 1 t/h of plastics wastes costs ca. € 1.4×10^6. The cost of operating the process, including chlorine separation but not chlorine disposal is estimated at ca. 100 €/t. With equipment now available, plants with capacities of up to 20 t/h are conceivable.

Partial Oxidation. In the partial oxidation process, heavy oil is converted to synthesis gas, a feedstock for the production of methanol, urea, and other basic chemicals. The heavy oil is heated to 250 °C and mixed with oxygen and steam, then atomized into a reactor. Part of the oil burns, supplying the heat to bring the process up to 1300 – 1500 °C. The product gas mixture consists of ca. 45 % carbon monoxide and ca. 45 % hydrogen, with 10 % carbon dioxide, which must be removed by scrubbing.

It would also be possible to replace the heavy oil with a synthetic heavy oil made from mixed plastics wastes in an degradative extruder, fluidized-bed reactor, or melting tank. Figure 47 shows schematically how a Shell process syngas plant might be combined with a degradative extrusion system handling mixed plastics wastes.

Process engineers at Farbwerke Hoechst have developed a fluidized-bed partial oxidation process that operates at 750 – 800 °C. The products are designed to be basic chemicals needed in large quantities in the chemical industry (Fig. 48). The results of the calculation show that this process is only partially competitive with landfills. The ESPAG plant at Schwarze Pumpe, using reactors originally designed for briqueted lignite, has already processed 20 000 t of waste plastics (packaging) together with lignite briquetts to produce town gas. The company is now converting its plants to make methanol from the gas [168].

Total Oxidation. Organic substances, such as mixed organic wastes that also contain plastics (e.g., household waste or shredder waste), can be treated with oxygen at high temperatures (>1500 °C) and completely converted to carbon dioxide and water vapor without any residual toxic hydrocarbons remaining. Figure 49 shows a closed cycle such as might be achieved with

such a process. By operating under substoichiometric conditions and metering hydrogen or hydrogen-rich substances into the off-gases, a synthesis gas can be made by reduction; this can be used in producing basic chemicals such as methanol. Some possible hydrogen-rich compounds (besides used oils) are polyolefin wastes liquefied by degradative extrusion.

Figure 50 shows a schematic of how such a plant might be built [169]. This system is especially suitable for converting mixed and contaminated plastics- containing wastes without pretreatment. It is equipped with a rotary kiln that is insensitive to melting thermoplastics. Because the combustion gas is pure oxygen, the volume of off-gas is only ca. 25 % of that in an air combustion plant, chiefly because nitrogen is not present. The combination has the following advantages:

1) The volume of pollutants is reduced to ca. 25 % compared to air as combustion gas
2) The off-gases have a high concentration of carbon dioxide (nearly 50 %), which permits the gas to be recovered and converted to synthesis gas, as shown in Figure 49.

The rotary furnace in Figure 50 functions as the oxidation reactor and is linked to a chemical plant via the gas- cleaning stage (removal of sulfur and chlorine compounds). In the example shown, the downstream plant makes urea solution.

Figure 49. Total oxidation of plastics wastes with reduction of tail gases in order to produce synthesis gas for synthesis of methanol and polymerization of polyoxymethylene (closed cycle)

7.2.4. Combustion (Energy or Thermal Recycling)

The expression "energy recycling" refers to utilizing the heat content of plastics wastes. Common plastics are an excellent fuel; polyolefins have a higher heating value than fuel oil (see Fig. 51), are cleaner, and contain no toxic or unpleasant species such as sulfur. Because polyolefins account for ca. 65 % of plastics in household waste and the other plastics in such waste also have high heating values, the average 7 % content of combustible plastics enables waste incinerators to save ca. 20 % of the fuel oil that would otherwise be needed for auxiliary firing. The proposition that it is economically desirable to utilize at least the energy of the plastics wastes contained in refuse is not disputed among

Figure 50. Combination of combustion with pure oxygen and chemical plant utilizing synthesis gases, for the conversion of shredder light fraction to urea solution

experts. This is even regarded as an alternative energy source for the future [170], [171]. Furthermore, this form of waste disposal cuts the volume shipped to landfills to ca. 10 % when conventional combustion is used. By using high-temperature combustion plant with oxygen and, e.g., a rotary kiln, a vitrified slag can be obtained that even retains heavy-metal oxides in noneluable form. Such slags can be used as construction materials, reducing the volume deposited in landfills to < 1 %.

Figure 51. Comparative table of heating values

7.2.4.1. Combustion in Waste Incinerators

The 7 % content of plastics in household waste is viewed by noted experts [172] as desirable for the operation of modern waste combustors, since the high heating value makes it possible to economize on other energy sources. Some 20 % of the fuel oil required as an auxiliary heat source for unsorted household waste can be saved [172], [173].

7.2.4.2. Shredded Waste as Fuel for Sewage Sludge

Tests in Bayer's rotary-kiln waste incinerator [174] have shown that the organic components of the shredder light fraction have a high heating value of > 18 MJ/kg, 50 % of that of coal. Burning this fuel produces no dioxins or other detrimental effects. Nevertheless, because of contamination with toxic used oil, shredder waste from automobiles is barred from normal waste-combustion facilities in Germany. Therefore, the concept being pursued is to mix shredded waste with sewage sludge and burn them together [175]. Tests have shown that this can save the fuel oil otherwise required for sludge combustion [176]. Heavy metals are fixed in the ash together with other toxic components already present there, albeit in a readily recoverable form. After the valuable heavy metals have been reclaimed, however, the ash residues must be dumped in landfills.

7.2.4.3. Combustion with Pure Oxygen [177]

Rotary kilns have proved best for the combustion of thermoplastics or wastes that contain large amounts of thermoplastics. If the furnace is fed with oxygen instead of air, the plant, and especially the flue-gas cleaning unit, can be downsized due to the absence of nitrogen. The reduction in volume by $> 75\,\%$ has other advantages, such as a very high adiabatic temperature, better efficiency, and less residue for landfill. Because of the advanced flue-gas cleaning techniques now used, combustion with oxygen ensures that emission standards will easily be met. A plant based on this concept corresponds to the combustion reactor on the left-hand side of Figure 50. Figure 52 shows an energy and mass balance for a plant of this kind processing 1 t/h of shredder light waste (18 MJ/kg). The heat generated in the system is utilized to heat the liquid oxygen for the cooling and condensation of CO_2, which is produced for industrial use.

Because the high adiabatic temperatures involved in combustion with concentrated oxygen necessitate cooling of the furnace, which can be accomplished by admitting unheated wastes or by recycling the stack gas, sludge from gas cleaning and dust from the filters are returned to the furnace and thereby incorporated in the slag, thus further reducing the volume going to landfills.

Other pollutants, such as gaseous chlorine and sulfur compounds must be removed from the flue gas before it is released to the atmosphere.

The energy required to produce oxygen is $0.5\,kW/m^3$, which is roughly half of the electrical energy generated in 1 t/h plants. Liquid oxygen costs $0.09\,€/m^3$ O_2 for major consumers. If the energy to make liquid oxygen is available, the price drops to $0.02\,€/m^3$.

Extra costs (disposal costs) for the combustion of shredded waste in plants of this kind are estimated at 130 and 230 €/t.

The process would offer the following advantages:

1) Due to the very high temperatures, a glass-like liquid slag is produced. Toxic heavy-metal oxides are fixed in noneluable form in this slag, which can therefore be used as a building material. Glass wastes would thus be desirable in the wastes fed to the process.
2) The volume of stack gas produced is only about a third as much as in combustion with air. This means that
   a) Investment costs are lower
   b) Very high temperatures are attained without supplementary heating
   c) Operating costs are low
   d) There are no emissions that would pollute atmosphere, soil, or water

7.3. Solvents

7.3.1. Introduction

Origin, Quantities, and Composition of Solvent Wastes. Organic solvents are employed in many industrial processes: in extraction and dispersion, extractive distillation, gas chromatography, chemical reactions, and recrystallization; in the production of paints, pickling agents, printing inks, rubber solutions, films, synthetic fibers, and plastics and resin solutions; for degreasing and chemical textile cleaning; and as aerosol propellants.

According to a nationwide examination of shipping documents for hazardous wastes, the quantity of organic solvents and solvent mixtures used in Germany in 1987 was ca. 385 000 t. Among the substances not included in this figure are cold cleaning agents and plasticizers. Some 38 % of the total represents halogen- containing solvents or solvent mixtures, while ca. 62 % is halogen-free [178].

Because of the wide variety of solvents and solvent applications, solvent wastes vary widely in composition as well as nature and content of impurities. Furthermore, used solvents are often collected in mixed form.

Environmental Relevance of Solvent Wastes. A large proportion of organic solvents are "hazardous wastes" as defined in § 2 Section 2 of the Federal Waste Act (Abfallgesetz) of August 27, 1986 [179] and are thus subject to accountability. Such substances pose hazards to human health, the atmosphere, water, and soil and are explosive or combustible.

Humans absorb organic solvents mainly via the respiratory tract and the skin. The resulting

Figure 52. Energy and mass balance of a shredder waste (18 MJ/kg) incineration plant operating with pure oxygen (Renz, Bu, Doll)
a) Combustion; b) Sulfur removal; c) Nitrogen removal; d) Aftercooler; e) O_2 preheater; f) Steam generator; g) Pump; h) Condenser

effects depend on the solvent itself, the quantity present, and the time for which it acts. Short, high exposures can lead to acute harm to the organism. The intake of small quantities over long spans of time can cause chronic diseases.

Solvents are absorbed and accumulate in fatty cells (nerves, brain, bone marrow, body fat, liver, kidneys), causing damage specific to the solvent and organ.

7.3.2. Processing of Solvent Wastes

7.3.2.1. General Aspects

Legislation requires that operators of facilities subject to regulatory approval minimize residues through abatement and recycling practices (§ 5 Section 1 No. 3 of the Federal Pollution Control Act, BImSchG [180]. Abatement practices include process optimization and/or modification as well as internal treatment and recycling units. External recycling takes place in central facilities. The recyclates are forwarded to the producer or returned to the economy as market chemicals.

Unmixed solvents with low impurity contents can generally be treated more readily than solvent mixtures with high concentrations of impurities. The prerequisite for effective, economical recycling of solvents is therefore that used solvents be collected separately. They must at least be separated into halogen- containing and halogen-free solvents, but it is best if solvents are collected individually.

A regulation concerning the acceptance and recycling of used halogenated solvents by the seller came into force on January 1, 1990 [181]. This regulation mandates that users of solvents collect residues separately and bans the mixing of halogenated with halogen-free solvents.

Methods used to purify waste solvents and solvent mixtures include:

Mechanical processes
Screening
Filtration
Sedimentation

Thermal processes
Distillation

Azeotropic distillation
Vacuum/pressure distillation
Hydrogenation
Gasification
Thin-film evaporation
Condensation
Chlorolysis
Extraction
Adsorption/absorption

Physicochemical processes
Freezing-out of water
Neutralization
Desiccation

The processes are essentially the same as those used to refine crude oil by removing solids, drying, eliminating inorganic components (salts), and separating into organic components or substance classes. Detailed process descriptions of methods can be found in [182–184]. Methods specially employed for the recovery, treatment, and recycling of solvents are summarized in [178], [185], [186], and elsewhere.

7.3.2.2. Mechanical Separation of Solids

Techniques used to separate solids and liquids include filtration, sedimentation, and centrifugation.

Filter presses and multicompartment drum filters are proven devices for separating solids from organic liquid systems. Simple gravel filters and centrifuges are less widely used. Equipment is fully described in the literature [187], [188].

In filter presses the slurry to be separated is inlet to individual chambers formed by frames and perforated plates that can be moved relative to one another. The plates are covered with filter cloths. The liquid phase can escape only by passing through the filter cloths to the discharge. The solids remain as a cake on the cloths. Separation can be speeded up by squeezing the filter plates together. When the filter cake has reached a certain thickness and interferes with or prevents further filtration, the press must be opened and cleaned. Thus filter presses can only be operated in batch mode.

Drum filters (Fig. 53) are more suitable for continuous operation. The drum, divided into chambers and covered with a fabric filter, rotates in the filter tank containing the slurry. A special valve imposes a vacuum on the chambers that are in the slurry. The liquid phase passes into the chambers and is drained off, while the solids remain on the filter medium to form a cake. When the filter chambers rotate out of the tank, the cake can be washed and dried by vacuum. It is then removed by a scraper. Compressed air or steam can be applied to the chambers to aid separation. After cake removal, the fabric may be washed. The cycle then begins over again.

7.3.2.3. Treatment of Halogenated Solvents

Highly chlorinated solvent wastes occur chiefly in the chemical industry. The following processes for their recovery and disposal are now installed or under development [189]:

1) Chlorination or chlorolysis to chlorinated hydrocarbon solvents
2) Solvent distillation
3) Dechlorination to hydrocarbons
4) Hydrogenation
5) Combustion
6) Physicochemical treatment

Of these processes, chlorolysis is most important economically. Chlorolysis converts the unavoidable residues of chlorinated hydrocarbons into valuable substances. Products with a low

Figure 54. Flowsheet of the Hüls low-pressure chlorolysis process [190]
CHC = chlorinated hydrocarbons.

degree of chlorination, for example from pharmaceutical and fine chemicals manufacturing, generally cannot be recycled by this method.

Numerous process variants have been developed for low-pressure chlorolysis producing tetrachloromethane and perchloroethylene simultaneously. Figure 54 shows a schematic of the Hüls low-pressure chlorolysis process.

Chlorinating cracking is performed in tubular or fluidized-bed reactors. The residues are high-boiling products, from which hexachloroethane and hexachlorobutadiene can be separated and recycled, and hydrogen chloride.

Chlorofluorocarbons (CFCs), used as refrigerants in air conditioning and cooling systems, represent a serious threat to the atmosphere because they damage the ozone layer. These substances can be recycled only if they are unmixed. Mixtures of refrigerants cannot be regenerated and must be disposed of in a hazardous-waste incinerator.

Before they are separated by distillation, refrigerants must be dried and deacidified. Figure 55 shows a schematic of a refrigerant purification process.

The high-boiling impurities are removed first. Acids are next eliminated and the product is dried before the gas phase is condensed and the condensate inlet to distillation. Byproducts and residues from the distillation step are inert gases and high-boiling constituents; these are forwarded to combustion plants together with other residues from the process. The regenerated refrigerant is led to a storage tank via a filter.

CFCs may not be produced, used, recycled, and placed back on the market after January 1, 1995. Global, progressive environmental thinking therefore demands that the focus should be shifted to safe destruction of these substances by incineration.

7.3.2.4. Treatment of Halogen-Free Solvents

Halogen-free solvents are becoming increasingly important as substitutes for halogenated solvents. The recovery and recycling of solvents from the gas phase depend on many factors (Fig. 56). The figure and the discussion below relate to halogen-free solvents and should apply by analogy to those containing halogenated products.

Processes for recovering solvents from the gas phase are based on the following principles:

1) Condensation
2) Adsorption on solids (activated carbon, silica gel, alumina, molecular sieves, polymers)
3) Absorption in liquids
4) Separation according to molecular size (membrane processes)

Adsorption on activated carbon and condensation have become particularly important. After adsorption the solvent is recovered by desorption, or the solvent-laden carbon is combusted. Combustion is generally practiced when gases with low solvent contents are cleaned and thus regeneration is not economical, or when many different solvents are collected together.

Figure 55. Flowsheet for purification of refrigerants by the Hoechst process [191]

Figure 56. Influencing factors and possibilities for recovery of organic solvents [192]

The methods used to separate adsorbent and solvent include steam desorption, vacuum desorption, and inert-gas desorption.

When steam is used for desorption, the process must include a water/solvent separation stage. Some methods are fractional distillation at atmospheric pressure or under vacuum, vacuum distillation with direct vapor compression, rectification in a thin-film evaporator, and batch distillation.

In the area of waste-air cleaning and solvent recovery, there are many process developments optimized for particular purification and separation problems, and for particular upstream and downstream processes [193], [194].

Fischer has devised a method for cleaning waste air and recovering all types of solvents [195] in an absorption – desorption plant. The scrub liquor and absorbent is heat-transfer oil, which collects the solvents from the gas phase. The solvent-laden oil is regenerated in the desorber, a specially designed vacuum distillation unit.

Halogen-free solvents and solvent mixtures arise chiefly from cleaning operations in print shops, painting and coating plants, and so

forth. These solvent wastes contain paint, resins, and other substances whose adhesive properties cause problems in treatment and may even render recycling impossible.

Figure 57. Distillation system for solvent recovery [197] a) Distillation tower; b) Forced-circulation evaporator; c) Condenser; d) Cooler; e) Separator; f) Drying tower; g) Condenser; h) Cooler; i) Solvent tank; j) Solids receiver

Contaminated solvents with low solids contents can be treated in a forced-circulation evaporator and concentrated to ca. 25 % solids. The circulation rate in the evaporator must be great enough to prevent blockage of the tubes.

For high solids contents, the standard distillation method may be unsuitable. Adhesive contaminants may have to be removed in thin-film evaporators or stills where vaporization takes place through a semipermeable layer that does not allow the contaminants to pass.

A thin-film evaporator consists of a heated cylindrical shell with an internal rotor that distributes the product as a thin film on the heating surface and scrapes the evaporation residues off the heating surface. The solvents evaporate and are collected in a downstream condenser. Residues are drained off at the bottom of the evaporator.

The processes used for solvent wastes free of adhesive contaminants include:

1) Mechanical recovery
2) Evaporation
3) Distillation (including single- and multistage, steam, vacuum, and azeotropic distillation)

Figure 58. Summary of painting processes

Often, a combination of these methods is necessary [196]. Figure 57 shows a distillation system.

Figure 59. Paint sludge by industry of origin in the Land Hesse, Germany, 1989

7.4. Paints

7.4.1. Introduction

Origin, Quantities, and Composition of Paint Sludges and Paint Wastes. Articles made of steel, plastics, wood, and other materials are coated with paints and varnishes in order to preserve them. The residues from coatings and coating operations represent a potential environmental hazard. These residues include paint sludges and paint wastes.

Paint sludges are produced whenever exhaust air laden with overspray is cleaned up by wet scrubbing (coagulation). More than two-thirds of the residues from painting installations are paint sludges [198].

Paint wastes are uncoagulated, dried, or dissolved paints originating at drainage (drip) points, as surplus, through improper or prolonged storage, or in cleaning operations.

The nature, quantity, and composition of these residues depend on the painting process and the branch of industry using the paint. Figure 58 lists the common painting techniques. Spraying with wet paints remains the most widely used technique. Comparatively large amounts of paint sludge arise from spray painting installations, especially in the case of simply compressed-air spraying [199].

Figure 59 presents a breakdown of paint sludge production by industry for the German Land of Hesse in 1989. The amount of paint sludge from plants requiring regulatory approval was 1625 t/a [200].

The 1987 tabulation of shipping documents for hazardous wastes in the Federal Republic of Germany gave a total output of ca. 144 000 t of paint sludge [201]. In Berlin, 3142 t of paint sludge was generated in 1991 [199].

Paint sludges vary widely in complexity and heterogeneity. They contain 50 – 70 % water and 1 – 10 % coagulant. The remainder is paint, which in turn contains vehicles, pigments, fillers, modifiers, additives, and solvents (see Fig. 60).

Figure 60. Composition of paint coagulate

Figure 61. Potential for waste abatement from regulated painting facilities in Hesse [200]

Environmental Relevance of Paint Sludge. Paint sludge generally contains solvents and/or heavy metals, and is therefore hazardous waste. These residues are for the most part disposed of in hazardous-waste combustion plants or deposited in hazardous-waste landfills.

When paint sludge is incinerated, the heavy metals liberated from certain pigments necessitate special methods of off-gas and residue treatment.

Virtually all the solvents in paints are released as atmospheric pollutants. In the Federal Republic in 1986, a total of 380 000 t of organic solvents was released into the air. Next to automobiles and trucks, the use of solvents is thus the largest emission source of volatile hydrocarbons [202].

Figure 62. Recycling and processing of paint sludge
HWR: hazardous waste repository; UR: underground repository

7.4.2. Recycling of Paint Residues

7.4.2.1. General Aspects

Operators of plants subject to regulatory approval must cut down the amount of residues generated and/or recycle their residues (§ 5 Section 1 No. 3 of the Federal Pollution Control Act, BImSchG [203]).

The production of paints involves major expenditure on plant, energy, and oil-based raw materials. Even if mixed with water, paint sludges are therefore of high economic value. The loss of paint coagulate in the Federal Republic of Germany in 1990 was estimated at 200 000 t with a value of around € 1.2×10^9 [204]. To conserve this value, internal processes that allow direct reuse should be chosen whenever possible, or external recycling should be practiced.

In painting shops paint residues can be greatly reduced by replacing conventional spraying by more paint-efficient application techniques. If the processes cannot be changed, process optimization and internal and external recycling must be used to reduce the quantity of residues to be disposed of.

Studies in regulated painting plants in Hesse, Germany, have shown, for example, that the 1989 output of paint sludge can be diminished by 51 % through suitable abatement and recycling practices (see Fig. 61).

Figure 62 shows the recycling and disposal options. Deposition of paint sludges in landfills is no longer permitted [205].

7.4.2.2. Internal Paint Recycling

Direct Recovery with Collection Equipment. Overspray is intercepted by appropriate devices and removed from them by doctor blades, solvents are added, and the product is returned to the painting process. Belts and disks are proven types of collection equipment. These direct paint recovery methods are particularly effective in spray processes where the particles are subjected to high acceleration and their trajectories are highly stable in direction (e.g., airless spraying). Figure 63 shows a process using a disk, which can recover 70 – 90 % of the overspray.

Figure 63. Disk-type overspray recovery system [198]
a) Solvent vessel; b) High-pressure solvent pump; c) High-pressure solvent feed line; d) Intermittent solenoid-actuated valve; e) Stainless steel disk; f) Stainless steel doctor blade; g) Nozzle assembly with cover; h) Replaceable funnel

Internal Recycling of Water-Based Paint. Water-based paint overspray is already intercepted by scrubbing and treated so that it can be recycled to the spray system. This kind of recycling is already in use for water-based baking enamels (which do not harden spontaneously) and has been implemented on a pilot-plant scale for airdrying water-based paints. Ultrafilterable latex paints for wood, commercially available since September 1992, permit internal recycling of water-based paints in the furniture industry [199].

The prerequisites for internal recycling are that:

1) The recirculating water contains no contaminants
2) The paint is "stable" (does not break down when highly diluted)
3) The fraction of overspray is not so great as to make the paint unusable (even small shifts in pH can cause coagulation)

The following processes (paint concentrators) can be used singly or in combination to separate the recirculating stream into a paint stream and a water stream:

1) Mechanical separation (decanters, centrifuges, etc.)
2) Ultrafiltration
3) Vacuum evaporation
4) Electrophoresis

Mechanical separators, however, are used only in combination with one of the other three methods.

The most important method for concentrating water-based paints is ultrafiltration. Vacuum evaporation and electrophoresis have serious drawbacks and, at present, can be used only in combination with other processes.

Figure 64 shows a flowsheet for internal recycling of water-based paint by ultrafiltration. The overspray is intercepted by a water curtain; no coagulant is used. The loaded scrub water is then fed to the filter unit, where it is separated into a low-paint substream, to be returned to the scrubbing process, and a paint-rich substream. The recovered paint is mixed with fresh paint and delivered to the automatic spray head. The maximum content of recycled paint is 35 – 45 %.

Figure 64. Internal recycling of water-based paint by ultrafiltration [199]

Figure 65 shows a more complex process for recycling of water-based paint in which a variety of concentrators are used. Undissolved paint particles are removed in the separator and returned to the paint tank (as recyclate 1). The liquid phase (thin paint) goes to the ultrafiltration unit, where it is enriched to a concentration suitable for electrophoresis.

7.4.2.3. External Paint Recycling

Recycling. The aim of recycling is to return the paint sludge to the process in one of the following forms:

1) Reconditioned paint
2) Base material for paint production
3) Base material for use in insulating materials, filler, moldings, and aqueous dispersions

The reconditioning of paint sludge to obtain reusable paint or base materials for paint preparation has the following prerequisites:

1) Neutral to weakly basic agents are used for coagulation to avoid denaturing the paint structure
2) Different paint systems are not mixed
3) Paint wastes are collected by color whenever possible
4) The scrub-liquor stream of the painting plant is kept free of other wastewaters and other wastes

Figure 65. Complex water-based paint recycling system with various types of concentrators [206]

Figure 66. Flowsheet for reprocessing paint coagulates by the Envilack process [201]

At present there is only one industrial method (the Envilack process) by which paint sludge can be reprocessed into new paint or base materials for the preparation of paint [199]. Another method (the Kluthe process) is now in development and has been tested on a bench scale [207].

The Envilack process (see Fig. 66) includes the following steps: dewatering, viscosity adjustment, purification, and separation into vehicle and pigment fractions. The process also permits reprocessing of paint sludge into new paint. If the conditions listed above are fulfilled, the following types of paint can be reprocessed:

1) Alkyd – aminoplast baking enamels
2) Acrylic resin paints and acrylate – aminoplast combinations
3) Polyester, epoxy, and melamine resin paints
4) Oxidizing drying paints

5) Physically drying paints

A 5000 t/a Envilack plant has been brought on stream in Duisburg, Germany. An expansion to 12 000 t/a is planned.

The Kluthe process processes paint sludge by distillation or extraction. The end products are a solvent phase, a vehicle fraction, and a pigment/filler fraction. This process can again be used only when the prerequisites cited above are fulfilled.

This vwk/GFR process [208] developed in 1990, yields an aqueous phase, an organic phase, and solids. This is less a paint sludge recycling process than a method of converting paint sludges to an easily handled form that facilitates recycling. A full-scale plant with a capacity of 6000 t/a has been put in service.

The process includes the following steps (see Fig. 67):

1) Drying of paint sludge with heat-transfer oil
2) Condensation of the gas phase from first step
3) Separation of the resulting liquid phase into organic and inorganic phases

The solids discharged from the process can be used in a variety of ways:

1) Auto underhood insulation, rear-window shelves, and other molded parts for the automobile industry
2) Insulating mats
3) Aggregate in cement production and brickmaking
4) Filler for plastics dispersions

Hydrogenation and Gasification. At Bottrop, VEBA Öl has operated a 200 000 t/a refinery residue processing plant since 1977 (see Fig. 68). About one-third of plant capacity is reserved for recycling special feedstocks, including distillation residues and paint sludges. The sludges must be inlet to the process in a dried, pneumatically conveyable form; there is currently no drying capacity at Bottrop.

The Bottrop plant can also hydrogenate plastics, thus making residues from resin-impregnating plants available for recycling even though relatively small quantities (a few t/a) make this an economically marginal proposition.

In addition to hydrogenation, organic residues (plastics, resins, etc.) can be processed in gasification systems like the one at Energiewerke Schwarze Pumpe. The same holds for resin wastes from impregnation plants, although small quantities make recycling more difficult in this case.

7.5. Metals

7.5.1. Introduction

Metal recycling can mean recycling of metal wastes to reclaim the metals, or recycling of nonmetallic compounds that contain metal cations to obtain the metals. This section deals only with compounds that were already in metallic form and became waste during production or consumption or in the course of recycling. Thus the winning of metals from primary resources and the wastes associated with these processes are not covered; the relevant waste sources in the product life cycle, which begins with the original shaping (e.g., casting or molding) of the metals, are considered.

Figure 69 shows the stages in metal recycling, based on VDI Guideline 2243 [209]. Each branch entails a decision whether a recycling path is available by which the waste can be recycled to a metal or other product in an economically and environmentally acceptable way and returned to production or consumption. The term metal recycling is used only when the result of recycling replaces a construction material or manufactured product derived from primary resources. Figure 69 does not reflect the fact that recycled substances and products can be forwarded to a process or use different from the initial one. According to the German Recycling Act (Kreislaufwirtschaftsgesetz) of July 8, 1994, which conforms to EC provisions, all process results that are not product must be viewed as wastes if they are not off-gases or wastewater. Wastes are classified as wastes for recycling and wastes for disposal (waste processing and landfill disposal). For example, production scrap becomes wastes for recycling.

In what follows, "recycling of production wastes" (Fig. 69, box 2) refers to wastes from the process chain, beginning with initial shaping and ending with fabrication of the finished product. In recycling during product use (box 4),

Figure 67. Flowsheet of the vwk/GFR process for processing paint sludge

Figure 68. VEBA Öl hydrogenation process
a) Preheater; b) Liquid-phase reactor; c) High-temperature separator; d) Gas-phase reactor; e) Gas scrubbing; f) Low-temperature separator; g) Vacuum distillation; h) Stabilization

in contrast to all the other forms of recycling, the form of the product or component is not broken down. The product or component is put to new use after reconditioning (according to VDI 2243 [209]).

The recycling of product wastes is subdivided into product-specific recycling (box 6), material-specific recycling (box 8), and recycling of material wastes (box 10). In product-specific recycling, the processes are oriented to particular product groups or product- components, such as vehicles and batteries. Material-specific recycling and recycling of material wastes can be regarded as subclasses of product-specific recycling. In material-specific recycling, processes are adapted to a particular material or to particular material groups, such as the arc furnace for steel scrap and the salt-bath furnace for aluminum scrap. In recycling of material wastes, alloys and assemblies are subjected to metallurgical processes to recover their metals separately, as for example in secondary copper smelting.

While the feeds to the above recycling processes are generally metallic, nonmetallic wastes from the other processes are introduced into the recycling of residues (Fig. 69, box 12)

Figure 69. Routes for metal recycling

and refined to metals. Examples include grinding slurries from product finishing and salt slags and flue dusts from material-specific recycling and material waste recycling. Often residue recycling is integrated into the other recycling paths, so that the boundaries between forms of recycling are not always clear. Overlaps with residue recycling occur particularly in production waste recycling, where not only metallic but also nonmetallic wastes are treated.

The structure of metals makes it possible, in principle, to recycle them with no loss of quality. Recycling is subject to not only economic but also environmental and technological limitations. Environmental limits are encountered when more primary resources are consumed in and more environmental burdens result from recycling than are replaced by the reclaimed metals. Technological limits occur where process development is not yet justified on economic grounds.

Because of the large number of metals, their widely varying uses, and the resulting range of recycling routes, it is not feasible to treat metal recycling in a comprehensive way. Instead, significant recycling options for the economically most important metals based on waste products and wastes are presented.

7.5.2. Production Waste Recycling

In view of the restrictions stated in Section 7.5.1, the only criteria for classifying waste sources are manufacturing processes. Wastes are attributed initial shaping, forming, separation, and surface coating, and are also classified as new scrap, plant-return scrap (home scrap), or primary wastes.

Initial Shaping. Typical processes for the initial shaping of metals are the various forms of casting. Metal wastes from casting are crop ends

(lost head and base) in continuous ingot casting, gate and riser systems in shape casting, and aborts and metal samples. If these metal wastes are collected separately by composition, they can be returned directly to the melting process. Nonmetallic wastes generally arise through contact with atmospheric oxygen. Aluminum, a relatively reactive metal, forms a dross that must be conditioned in a special process (Section 7.5.2). If, however, the relatively noble metal copper absorbs oxygen, it need only be reduced by poling in the anode furnace, the final pyrometallurgical process before the manufacture of electrolytic copper.

Forming and Working. With regard to the wastes generated, forming is subdivided into hot and cold forming.

In hot forming processes such as hot rolling and forging, oxidation products (e.g., scale) are formed along with wasters, cuts, and samples. Scale, an oxidation product of iron, does not adhere to the steel and can be removed with high-pressure water during hot rolling. Metallic wastes are returned to melting, while scale is sintered and reduced in the blast furnace together with iron ore concentrates.

Wastes from cold forming processes (e.g., rolling, drawing, deep drawing, and bending) include cuts and specimens of not only single materials but also composites. Such a composite consists of several metallic materials or of metallic and nonmetallic materials. While metal wastes from single materials can be fed back to the respective melting operations, composites have to be subjected to a more differentiated production waste recycling. It must be decided whether all substances are to be recovered from the composite or not. Surface coatings are collected separately if they consist of a valuable metal or if they would interfere with the recovery of the parent metal. Silver, for example, occurs as thin coatings on materials used in the electrical and electronics industries. It can be removed from the substrate with sodium cyanide solution to which aromatic nitro compounds have been added as oxidizing agents. Copper and copper alloys are, however, attacked by the same agents. To recover the silver, the resulting solutions are subjected to ion exchange, electrolysis, or cementation, similarly to waste solutions from electrolysis [210].

To recover tin from tinplate waste containing 7 – 4.5 g of tin per kilogram of sheet steel, the plate composite is treated with gaseous chlorine in a reaction tower. The exothermic reaction yields tin tetrachloride $SnCl_4$, which is distilled off and condensed in a cooler. It can be used in making pink salt $(NH_4)_2SnCl_6$, organotin compounds, and other products. Tinplate scrap can also be electrolytically detinned by anodic dissolution in 5 – 10 % caustic soda solution, giving sodium stannate. Paint coatings are removed from the scrap with high-pressure water and hot soda solution; the cleaned scrap is then placed in movable, perforated steel balls or baskets. If the electrolyte made in this way contains Pb, Zn, As, or Sb, these are precipitated with sodium sulfide. Tin deposited on sheet-iron anodes from the electrolytes (50 g/L tin) is recovered by melting and may be refined again by steam injection. The detinned electrolyte (2 – 10 g/L tin) is returned to anodic dissolution [211].

Another way of recycling purely metallic composites so that none of the substances contained in them is lost is melting without prior separation. This is possible only in the case of material compatibility [212], i.e., that no element present in the wastes leads to a violation of the specification for the construction material produced by melting without dilution by primary metals. Tinned copper can be melted to obtain bronzes and red brass. A nickel- and chromium-plated steel can also be utilized in making chromium – nickel steels without prior separation. Melting must be carried out with very low oxygen partial pressures, since otherwise the chromium oxidizes and forms slag. Nonmetallic components are generally not recovered from composite materials.

Cutting leads to formation of punching waste, shearing scrap, and other materials. These correspond to wastes from cold-forming processes and are treated as such. Metal-removing operations yield turning, hobbing, milling, boring, or saw chips, depending on the technique and the geometrical form of the tool used. These operations are done with coolants, which consist of ca. 10 % mineral oils, water, and a variety of additives. Before the chips can be inlet to a melting process, they must be de-oiled to comply with emission limits for organic substances. Oil can be removed by centrifugation and wash-

ing. Grinding slurries are processed when they contain valuable metals or compounds of such metals.

The U.S. Bureau of Mines has developed a hydrometallurgical process for recovering cobalt, chromium, manganese, nickel, and tungsten from grinding slurries generated in the machining of sintered metal alloys [213]. A slurry containing (after drying and de-oiling) 15.1 % cobalt, 19.8 % chromium, 31 % iron, 3.6 % manganese, 11.5 % nickel, and 5.1 % tungsten is produced in a quantity of about 1600 t/a in the United States. The de-oiled and washed slurry is leached in hydrochloric acid with addition of gaseous chlorine. The solution contains Co, Cr, Fe, Mn, and Ni; the residue contains tungsten. From the leach residue, Na_2WO_4 is obtained by dissolution in caustic soda, then calcium tungstate $CaWO_4$ by precipitation with calcium chloride. From the first leach liquor, iron, cobalt, manganese, nickel, and chromium are obtained in succession by solvent extraction of their chlorides. The residual solution can be reused for leaching. All products have impurity levels below the specified levels and are thus salable. In the laboratory-scale plant described, 90 % of the tungsten and over 97 % of all other values were recovered [213].

The grinding of permanent magnets made from iron alloys containing aluminum, nickel, and cobalt yields residues containing 10 – 15 % cobalt and 4 – 7 % nickel. Sulfur and carbon present in the grinding slurries interfere with the recovery of these valuable metals. The sulfur originates in the binder of the abrasive, the carbon from the coolants used. These substances must be removed before the valuable metals in the grinding slurries can be reused directly for permanent-magnet production. A process devised by the U.S. Bureau of Mines consists of desulfurizing and de-oiling at 112 °C with tetrachloroethylene, which is recycled, drying and grinding the residue, screening and magnetic separation to remove the main component of the abrasive (Al_2O_3), oxidative roasting at 950 °C to remove residual sulfur and carbon, and reduction of the metal oxides at 1200 °C with hydrogen [214]. The result is a metal powder that contains > 95 % of the cobalt, nickel, and iron, as well as ca. 90 % of the copper fed to the process. The contents of residual sulfur and carbon in the metal powder are 0.01 % and 0.06 % respectively. This material can be added directly to the melt for the fabrication of permanent magnets; the ca. 30 % Al_2O_3 in the recycled product is slagged on melting [214].

Pickling solutions are generated when metals are etched or cleaned with acids such as hydrochloric acid. The consumption of hydrochloric acid for this process (as commercial 37 wt % acid) is 0.3 – 3 kg/t steel; without regeneration it would be 20 – 35 kg/t steel [215]. The iron(II)-loaded pickling solution is treated with HCl gas, whereby $FeCl_2 \cdot 4\,H_2O$ crystallizes out and is separated. The solution is recycled to the pickling process. The iron chloride is heated to ca. 300 °C in a stream of oxygen and steam, giving Fe_2O_3 and HCl. This HCl gas is used to treat iron-laden pickling solution to crystallize iron chloride. The hydrochloric acid thus moves in a closed circuit [216]. The ca. 4.8 kg iron oxide generated per tonne of steel treated is used as a raw material in other processes [215].

Coating. In electrolytic operations, process water is generated by rinsing and the disposal of short-lived process baths; this water has to be purified. The addition of milk of lime or caustic soda, along with flocculation aids if necessary, converts the dissolved heavy metals to sparingly soluble hydroxides or hydrated oxides, which precipitate to form "cell mud," which is then mechanically dewatered. In the form of hydroxides or hydrated oxides, the mud contains metals that are to be electrolytically deposited on the workpiece. Table 12 lists average metal levels in U.S. electrolysis cell muds.

These muds can be treated by hydrometallurgical or pyrometallurgical methods. Standard hydrometallurgical processes include leaching, solid – liquid separation, cementation, and precipitation. Chlorides, fluorides, phosphates, ammonium, and organic substances interfere with the processes. Even though hydrometallurgical processing of cell muds exhibits high flexibility, the small amounts of muds (<100 t/a for most electrolytic processes) and the variations in mud composition, depending on the electrolytic operation, make these processes very cost intensive [217]. Pyrometallurgical processes are less flexible but have cost advantages. The pyrometallurgical processes used for treating cell muds are the same ones developed for the refining of primary resources or in some cases for other

Table 12. Average analyses (wt %) of electrolysis cell muds in the United States (1991), arranged according to dominant metal [216]

Number of samples	Cu	Ni	Pb	Zn	Cr	Fe	Moisture
171	16.4	7.5	0.6	3.6	1.4	4.7	43.3
148	2.8	16.1	0.1	1.8	3.3	3.8	41.4
33	3.7	0.1	36.0	6.4	0.5	1.1	16.5
99	2.9	0.4	3.7	28.8	1.6	4.8	31.7
57	1.1	1.7	4.8	1.8	24.4	3.5	34.7

wastes. Such plants have high capacities, in the range of 50 000 – 300 000 t/a, which is at least a thousandfold greater than the output of cell mud from a plant. Any metallurgical process is suitable only for muds having the combination of metals for which the process was first developed and is now operated. With express approval for the use of cell mud as a secondary raw material, the following pyrometallurgical facilities are available [218]:

1) For muds containing cadmium, lead, zinc, and iron: the B.U.S. rotary-furnace volatilizing process at Duisburg [219]
2) For muds containing nickel, chromium, and iron: the Swedish Plasmadust process [220]
3) For muds containing zinc: the New Jersey process of Harzer Zink GmbH at Goslar [221]
4) For muds containing copper and nickel: the secondary copper process operated at Lünen by Hüttenwerke Kaiser AG (see Section 7.5.4.3) [222]

7.5.3. Recycling during Product Use and Product Reconditioning

Consumer and capital goods are taken out of use because they are defective, because they no longer fulfill their function properly, or because they no longer correspond to the state of the art. Such a waste product must be examined (Fig. 69, box 3) to see whether reconditioning (box 4) is an option. In reconditioning, the form of the product or component is not broken down. Often not the entire product is reconditioned, only components of it, such as automobile engines or the roll sets from hot- and cold-strip rolling mills. One then speaks of making replacement products [223]; this is a subset of product reconditioning. The following steps are involved:

1) Completely disassemble item
2) Clean parts
3) Inspect and sort parts
4) Recondition or replace unusable parts
5) Reassemble item

Products reconditioned in this way are of equal quality to new products. Because the product form is preserved and products/components/parts are only partially reworked, they can be kept in service at a relatively low cost. The focus in component reconditioning is on machining operations such as turning, milling, boring, and grinding. This work makes up some 45 % of total reconditioning effort for a gasoline engine from an automobile [223].

The metal wastes generated in this process can be recycled as production wastes (Fig. 69, box 2) if they are unmixed and of known composition, and as wastes otherwise (box 10). Parts that can no longer be reconditioned pass on to product waste recycling (boxes 6, 8, and 10). Other examples of product reconditioning include household appliances such as water heaters, all kinds of power tools, office equipment such as typewriters and copiers, and automatic dispensers for cigarettes, beverages, and so on. Reconditioning applies particularly to metallic materials, since these can be machined without problems, restored to specified dimensions by buildup welding, and heat-treated or otherwise treated to impart the required properties. Partial disassembly of automobiles allows a 15 % reuse of components (motors, transmissions, generators, etc.); the reuse figure is 5 – 10 % for computer equipment [224].

7.5.4. Product Waste Recycling

Product waste recycling (Fig. 69, boxes 6, 8, and 10) includes product-specific and material-specific recycling as well as recycling of material

wastes. In contrast to recycling during product use (reconditioning), here the form of the old product, component, or part is broken down.

7.5.4.1. Product-Specific Recycling

In product-specific recycling, the recycling route is oriented to a particular product or product group. Product-specific recycling can be classified in a way that corresponds to the distinction between (discrete) manufacturing and (continuous) processing [224]. Discrete operations relate to disassembly (DIN 8580) [225], while all continuous operations in this context involve changes in the composition, properties, and nature of the substances. The continuous processing class is once again broken down into physical and chemical operations. As a rule, discrete operations precede continuous ones. In partial disassembly, components that are still functional or can be reconditioned are removed, as are those that would interfere with continuous processing and those that contain materials reclaimable after separation. In the case of an automobile, examples in the above order would be the alternator, the gasoline engine, and copperbased components. Table 13 lists the fractions of some consumer products that can be reconditioned and reclaimed, together with future target reclamation figures for Germany. The sums of the component reconditioning and reclamation fractions correspond roughly to the metal contents of these consumer products.

Table 13. Component reconditioning and reclamation of substances from used consumer goods (in wt %) [223]

Used consumer goods	Component reconditioning	Reclamation	
	1990	1990	Future
Automobiles	15	60.5	77.0
Washing machines		67.1	71.7
Dishwashers		58.0	88.0
Refrigerators		56.5	96.9
Computers	5 – 10	81.3	94.7
Televisions		5.0	83.0

7.5.4.1.1. Automobiles

The automobile is a highly complex consumer product. When it is taken out of service, it consists of:

1) Components that can be reused without reconditioning
2) Components that can be returned to use after reconditioning
3) Substances whose value justifies reclaiming them
4) Substances that interfere with reclamation

The average composition of a discarded 1993 auto with a total weight of 1126 kg [225], [226] was:

Steel	513.0 kg
Cast iron	104.5 kg
Aluminum	50.0 kg
Lead	10.2 kg
Copper	9.5 kg
Zinc	4.7 kg
Nickel	0.3 kg
Other nonferrous metals	32.3 kg
Plastics	248.0 kg
Glass	38.0 kg
Textiles	15.2 kg
Rubber from used tires	40.0 kg
Others	60.3 kg

These cars consist of 64.3 % metallic materials and 22 % plastics. Recent years have seen a marked reduction in the content of ferrous metals and a rise in the contents of aluminum and plastics.

Figure 70 shows the principal routes for auto recycling. Removal of fuel and fluids is followed by partial disassembly. Components such as the engine, alternator, starter, transmission, and so forth are either used as spare or replacement parts or reconditioned for reuse. As a rule, the lead – acid battery and the catalytic converter are also removed. Recycling practices for lead-acid batteries have long been established (see Section 7.5.4.1.3); the catalytic converter is of interest because it contains 1.7 – 1.9 g of platinum-group metals (see Section 7.5.4.1.2).

One purpose of automobile recycling is to reclaim the metals. The choice of method is governed not only by economics but also by the separation of heavy metals from ferrous metals. Heavy metals can impair both the service properties and the processability of steel, especially if several heavy metals are simultaneously present. Copper levels of 1000 – 1500 ppm should be aimed at, though high-tonnage steels can tolerate higher levels. For deep-drawing steels that contain tin and copper, the copper

Figure 70. Conceptual elements and material streams in automobile recycling [226], [228]

content must be still lower. Otherwise, thermally stable copper – tin compounds can form, which, unlike copper alone, do not redissolve in the iron after precipitation at grain boundaries. Studies on deep-drawing steels with 150 – 650 ppm copper have shown that the key mechanical properties (yield strength, tensile strength, reduction of area at failure, ultimate elongation) after hot rolling did not change as the tin content was raised stepwise from 80 to 250 ppm. Nor could alterations be detected in the cold-rolled strip [227].

Heavy metals such as zinc and lead, as well as tin in scrap iron, are vaporized at the temperatures prevailing in the oxygen converter or arc furnace and also in metallurgical recycling. Complete removal of heavy metals is not possible, however, because the activities of these metals also decline with decreasing concentrations in the steel melt. The majority of copper inlet with scrap remains in the steel together with ca. 60 % of tin. For this reason, care must be taken – especially in auto recycling – to remove copper and tin before metallurgical recycling. Separation and reclamation of the metals from autos is a substantial contribution to resource conservation. The removal of nonferrous metals from the auto can be performed by discrete assembly (or partial disassembly) operations or by continuous processing of shredder fractions. Of the ca. 2.6×10^6 autos discarded in Germany in 1992, ca. 85 % were shredded and ca. 15 % cut up in scrap shears or compressed in baling presses.

Shredder Route. After partial disassembly and removal of fluids, cars are mechanically reduced in size by the shredder. The selective action of the shredder disintegrates complete car bodies; ferrous components are compressed to fist-sized pieces. Components entrained in the exhaust air are removed in an integrated cyclone; this shredder light fraction has been disposed of in landfills, but studies are under way on reclamation of valuable constituents from the light fraction as well as extraction of the energy content as heat. The heavy fraction, 77 wt % of the inlet stream, is sorted on the basis of several physical properties. Besides magnetic separation to isolate ferrous scrap and pneumatic separation to recover nonmetals, other processes are becoming established. An example is eddy-current separation used to obtain nonferrous

metal concentrates. Methods are being developed for automatic identification and separation of metal mixtures by composition. The feed material must be largely free of interfering substances and must be disintegrated to the point that piece sorting is equivalent to material sorting (see Section 7.5.4.2).

The average mass balance for old cars put through shredders in the Federal Republic of Germany in 1990 shows that 70 wt % of the feed goes into the scrap-iron fraction, 23 wt % into the light fraction and 7 wt % into the mixed fraction consisting primarily of nonferrous metals. Figure 71 shows a breakdown of the mixed fraction (into aluminum, copper, zinc, and lead) for the same period. About 1 % of aluminum and 10 % of copper remain in the iron fraction, and this copper contributes to copper levels in the steel. Zinc is not present in the ferrous fraction, suggesting that the bodywork in question was mainly nongalvanized. The light fraction and iron fraction data give the losses as fractions of shredder feed. Under the mixed fraction, the fractions processable in metal foundries or smelters are indicated. These data may vary with age of the automobile and extent of disassembly.

Metallurgical recycling, developed and put through pilot tests by Voest-Alpine-Stahl and Mercedes Benz, is a novel method for processing automobiles after service. As in all other recycling approaches, the first step is removal of fuel and fluids. This is followed by partial disassembly aimed at maximum recovery of spare parts (i.e., reuse of assemblies and components) and the generation of fractions suitable for materials recycling. This partial disassembly step also determines the copper content of the steel to be made. An analysis of a middle- class 1980-model car shows that ca. 74 % of total copper is in the engine with accessories, the transmission, and the main electrical system. If the engine, transmission, starter, alternator, radiator, and 50 % of the main electrical wiring are removed, the remaining scrap steel contains ca. 0.2 % copper [228]. The time required to remove these components is ca. 25 min, and their removal lowers the total weight of the car by ca. 47 %. The scrap, still contaminated with about 100 kg of plastics and organic constituents, is baled and fed to the scrap melter. The melter is an enclosed shaft furnace, charged continuously and heated with natural gas/oxygen burners. Adhering plastics lower the energy requirement for melting by 30 – 40 %. In the high-temperature zone, organic substances are oxidized and go into the gas phase. Zinc, lead, and other heavy metals are vaporized and collected in a filter. In the upper part of the reactor, at temperatures above 1100 °C, dioxins and furans are destroyed. The lead – zinc dust obtained from gas cleaning is utilized in zinc smelters (Section 7.5.5). The steel produced in this way has a low carbon content and does not differ in quality from steels made by the shredderroute. This process has the advantage that for ca. 530 kg of material inlet to metallurgical recycling, 143 kg of light fraction does not have to be disposed of in the landfill as in the shredder process. Utilization of the energy content of residual organic substances results in a saving of primary energy, while the presence of residual inorganic components means that slag formers need not be added to the melt. The process has the disadvantage that the aluminum from the auto is lost as slag [226].

Complete Disassembly. The aim of disassembly is the separate and complete collection of components and substances that can be reclaimed or that must be classified as hazardous wastes, with appropriate interim storage, reclamation, or treatment of the collected materials. Disassembly can be carried out in either of two ways: line disassembly and island disassembly. Disassembly organized similarly to assembly is possible only in plants that are restricted to certain models of vehicles. Because car models are so diverse and are not yet designed for disassembly, this operation cannot be completely automated; it is therefore set up in open facilities with semiautomated conveyor lines. In disassembly, an automobile consisting of some 10 000 parts is broken down so that they can be sorted into about 10 – 15 pure material classes. When disassembly is done on the island principle, all work is performed in disassembly cells or islands. The disassembly line approach has the operations performed in sequence and at different locations; in this way they can be optimized and high capacities can be achieved. Island disassembly permits greater "depths" of disassembly. After disassembly, the body is baled in a press to the density of scrap iron for economical

Figure 71. Distribution of nonferrous metals among shredder fractions [226]

shipping. Preliminary removal of all nonferrous metals makes it possible to lower copper and tin levels in the scrap and thus improve the quality. The principal nonferrous metals present are aluminum from wheel rims, cylinder heads, and oil pans; zinc from a variety of die-cast parts; copper from engine parts, starters, generators, radiators, and cables; and lead from batteries and wheel-balancing weights.

Sheet-Metal Recycling. Contamination from surface coatings and automotive fluids enter the steel melt when auto scrap is fed to secondary steelmaking. Heavy metals and organic compounds must be retained by expensive filtration. A method has been developed by which body parts can be directly reused as sheet metal [229]. Large pieces of sheet metal, provided they are not damaged by rust or accidents, are removed, heated to remove coatings, and then straightened. This means that the steps of shredding, casting, rolling, descaling, and recrystallization annealing can be omitted. In comparison with steel-mill processing, the process yields an energy saving of ca. 97 %. The properties of the sheet metal are comparable with those of new metal.

7.5.4.1.2. Catalytic Converters

In 1987, automotive catalytic converters represented a demand for 35 t of platinum (out of a total consumption of 102 t), 7.3 t of rhodium (out of 10 t), and 6.4 t of palladium (out of 101 t) [230]. Consumption will rise, since virtually all used cars will have catalytic converters in the foreseeable future. Because of their average contents of 1.5 g platinum and 0.3 g rhodium the converters are removed from discarded autos before further processing [226]. Catalysts used in the United States also contain palladium. The ratio of platinum to palladium to rhodium is about 14: 7: 1. The platinum metals are supported on γ-Al_2O_3. Pellet-type catalysts consist entirely of γ-alumina, while in monolithic catalysts this material is applied as a gel or wash coat on the

surface of the honeycomb structure, made of iron cordierite $2\,FeO \cdot 2\,Al_2O_3 \cdot 5\,SiO_2$ or magnesium cordierite $2\,MgO \cdot 2\,Al_2O_3 \cdot 5\,SiO_2$. The pellets in a pellet catalyst weigh 2 kg on average; a monolith averages 1 kg with about 15 % γ-Al_2O_3. Both types have the same content of platinum group metals, so that the metal concentration in monoliths is about twice as high as in pellets [231]. The share of pellet catalysts in exhaust converters is declining.

The first step is to cut off the stainless steel case in which the actual catalyst is located, then remove the ceramic support material. The support is ground, homogenized, and analyzed to determine the noble metal content. Smelters or parting plants recover the platinum group metals by hydrometallurgical or pyrometallurgical methods. In hydrometallurgical processes, sulfuric acid is used to dissolve the material containing the platinum group metals: either the complete pellets or just the alumina coat from the cordierite monolith. Various combinations of separation and enrichment methods are employed [231]. In a method applicable to both types of catalyst the ground material is leached for 1 h at 160 °C with 1 % sodium cyanide solution. The dissolved platinum metals are precipitated by decomposing the cyanide complexes at 260 °C. Any lead present is not dissolved; it enters the leach residue [232]. The wet chemical processes are problematical because of the large amounts of wastewater and residues involved. The yield of platinum group metals is lower than that from pyrometallurgical processes.

In pyrometallurgical recycling processes, the catalysts are melted with a collector metal. Degussa has a lead blast furnace in which the platinum metals together with noble metals from other residues are collected in lead. The ceramic material is slagged, and the noble metal free slag is discarded. The resulting lead bullion is forwarded to the converter, where it is oxidized in the melt by oxygen or air. Oxides of non-noble metals dissolve in the litharge produced in this cuppelation step, leaving behind auriferous silver, an alloy of silver, gold, and the platinum group metals. The individual noble metals are won from this metal by standard methods [233].

If copper is used as collector, the catalysts are inlet to a standard copper recovery process. The noble metals accumulate in the anode slime of the electrolytic copper refining cell and are extracted from this in conventional fashion [233]. It is claimed that the highest recycling rates for platinum group metals are achieved with this technique, but the time from when the catalysts enter the process until the platinum group metals are obtained is much longer than in other recycling methods [231].

The Tetronics plasma furnace melts the catalysts with the addition of iron at temperatures above 2000 °C. Part of the silicon dioxide is reduced to silicon, so that the platinum group metals are collected in an iron – silicon alloy. The pulverized metal is treated with sulfuric acid under oxidizing conditions to dissolve the iron and silicon. The noble-metal concentrate in the residue is refined to the metals in a parting plant.

The recycling rate is in the range of 86 – 93 % for platinum and palladium, and between 81 and 87 % for rhodium [232]. Both the energy consumption and the recycling rate are lower in the hydrometallurgical processes than in the pyrometallurgical processes.

7.5.4.1.3. Lead – Acid Batteries

On average, automobile batteries weigh 16.5 kg and contain ca. 10 kg of lead (ca. 60 %). More than 50 % of the lead consists of sulfate and oxide paste. Of 78×10^6 lead – acid batteries in the United States in 1991, more than 98 % were recycled; the rate for Europe in the same period was ca. 90 % [232].

Figure 72 shows a flowsheet for mechanical separation of lead – acid batteries as practiced by Harz-Metall-GmbH, an operation of Metaleurop. The battery cases, made of polypropylene or, to a decreasing extent, hard rubber (ebonite), are mechanically broken up in the double-roll crusher. The sulfuric acid released is neutralized with milk of lime. By grinding, screening, and heavy-medium separation, the battery scrap is divided into metal, oxide, polypropylene, and ebonite fractions. Of these four, the ebonite is not processed further at present [234].

At Harz-Metall, the metal and oxide fractions are obtained in roughly a 1: 1 ratio; polypropylene accounts for about 4.5 % based on battery scrap. The oxide fraction contains 69 – 75 % lead, 0.3 – 0.5 % antimony, and 5.3 – 6.2 % sulfur, while the metal fraction contains 60 – 75 % metallic lead and 10 – 30 % lead in oxide form.

Figure 72. Flowsheet for physical processing of lead – acid battery scrap [234]
MF = metal fraction, OF = oxide fraction
a) Battery scrap storage; b) Feeder; c) Conveyor scale; d) Double-roll crusher; e) Magnet; f) Metal detector; g) Wastewater treatment; h) Hammer mill; i) Vibrating screen; j) Oxide classifiers; k) Hydraulic classifier; l) Plastics classifier; m) Pusher centrifuge; n) Polypropylene refining

The lead losses of < 1 % result from the 4 – 11 % lead content of the ebonite fraction. The oxide fraction is inlet to the rotary furnace; coal is added for reduction and iron filings and soda to fix the sulfur. The furnace product is lead containing 1 – 2 % antimony. The metal fraction is processed in the short rotary furnace, yielding lead with 3 – 4 % antimony. The low-antimony lead is refined to soft lead (99.97 % Pb), the high-antimony product to hard lead [233]. The difference between these secondary leads and primary lead (99.99 % Pb) is that bismuth and silver are not removed by the refining that takes place in recycling smelters [235].

In contrast to the above fraction-by-fraction process, the blast-furnace process (RSR in the United States, VARTA in Germany, Bergsøe in Denmark) dispenses with mechanical crushing into fractions. The battery case is automatically drained, so that whole, unground batteries can be charged to the blast furnace together with coke, limestone, and iron. The coke releases energy and establishes a strongly reducing atmosphere in the furnace. Organic components of the battery – the case material, spacers, and seals – contribute to the reducing atmosphere as well. Limestone and iron form a fluid slag with the inorganic constituents of the battery and the coke. Part of the iron, together with reduced sulfate sulfur, forms an iron – lead matte containing ca. 8 % lead. Nearly 90 % of the inlet sulfur is fixed in this way; the matte is contin-

uously discharged with the slag and separates from it because of the density difference. After solidification, the slag and the iron – lead matte can be mechanically separated. The top gas contains carbon monoxide, chlorides, and decomposition products of the plastics. It is combusted at 900 –1000 °C with a slight air excess, cooled, and passed through dust- collection equipment [236].

Plant used for recovering lead from batteries in the United States includes blast furnaces and, increasingly, reverberatory furnaces. The lead-bearing components of the batteries are processed in the reverberatory furnace with limestone, iron, and coke; the furnace discharges soft (low-antimony) lead bullion and an iron – sulfur matte. The slag is rich in lead oxide and contains most of the inlet alloy constituents; it is processed in the blast furnace or electric furnace to obtain hard lead and a slag that can be disposed of in landfills [232], [235].

7.5.4.1.4. Dry-Cell Batteries

Primary batteries are not rechargeable, in contrast to secondary or storage batteries. Various types of cells have anodes of zinc or lithium; cathodes of manganese dioxide, silver oxide, mercury oxide, or carbon; electrolytes of ammonium or zinc chloride, potassium hydroxide, or organic compounds; and cases of cardboard, plastics, and primarily steel. 1000 kg of such batteries, as collected, contain the following substances [237]:

Manganese dioxide	270 kg
Iron	210 kg
Zinc	160 kg
Graphite	60 kg
Ammonium chloride	35 kg
Copper	20 kg
Potassium hydroxide	10 kg
Mercury	3 kg
Cadmium	0.5 kg
Silver	0.3 kg

The composition varies with the proportions of different battery systems in use and due to fluctuations in cell composition. For example, the consumption of mercury for zinc – carbon and alkali – manganese cells fell from 30 t/a in 1986 to 5.5 t/a in 1988 [238]. In the Federal Republic of Germany, some 18 000 t of dry- cell batteries were sold in 1988; roughly one-third of these were collected for recycling.

The inhomogeneous mixture of dry batteries is subjected to thermal treatment either unsorted (Sumitomo and Recytec processes) or after preliminary sorting into button and cylinder types (Voest-Alpine and Clean Japan Centre processes). In the Recytec process, water, organic substances, and mercury are distilled and condensed, and the off-gas stream is cleaned with adsorption filters. After the solid residues are ground, manganese dioxide and zinc are leached out and separated by electrolysis. The ferrous components are removed from the insoluble residual fraction by magnetic separation. The remaining nonferrous metals are selectively dissolved with tetrafluoroboric acid and recovered separately in several electrolysis steps (zinc – cadmium, iron – chromium – nickel, copper – silver). In the Sumitomo process, fractional distillation is used to remove mercury (500 °C) and organics (800 °C), then the solid residues are fed to a blast furnace, where they are melted under reducing conditions at 1350 – 1500 °C. Zinc vaporizes and is condensed as the metal. Iron and manganese are discharged as an alloy that can be used in making ferromanganese or silicomanganese. A multistage off-gas treatment system recovers mercury and also ensures very low emission levels.

In the Voest-Alpine process, button cells are heated to 650 °C under reducing conditions to drive off mercury, which is condensed in metallic form. The residue is leached with nitric acid. The stainless steel scrap recovered after this step is forwarded to scrap storage for remelting. Treatment of the solution with hydrochloric acid precipitates silver chloride, which is reduced with zinc metal to obtain silver. In this way, silver, mercury, and stainless steel scrap, all of salable quality, are reclaimed from button cells. The wastes are zinc chloride and zinc and nickel slimes. Cylindrical batteries are ground in the Voest-Alpine process, the paper and plastics parts are removed by screening, and the scrap iron is recovered by magnetic separation. From the residue, mercury and zinc are successively vaporized and recovered as the metal or oxide. The residual mass can be converted to electrolyte (MnO_2).

7.5.4.1.5. Electronics Scrap; Circuit Boards

Because no unambiguous definition exists for electronics scrap, so the presence of circuit boards can be regarded as a first characteristic of this kind of scrap. Because electrical equipment also contains circuit boards, the broadest definition term would include such equipment along with computer, communications, and entertainment electronics. In Germany, 130×10^6 electrical and electronic devices with a mass of around 1.5×10^6 t are retired yearly. These old devices contain 30 000 – 45 000 t of circuit boards [240]. The average composition of electronics scrap in the United States (computers, telephones, relays, etc.) is reported as 30 % plastics, 30 % refractory oxides (15 % SiO_2, 6 % Al_2O_3), 40 % metals (20 % copper, 8 % iron, 4 % tin, 2 % each nickel, lead, and aluminum, and 1.2 % zinc), and 0.3 % noble metals [241]. The scrap analysis varies widely, depending on the components present and where they were manufactured.

The purpose of processing electronics scrap is to reduce pollutant levels (e.g., to remove capacitors containing polychlorinated biphenyls for underground deposition) and to recover metals, especially noble metals. The various routes for electronics scrap processing begin with preparation for hydrometallurgical or pyrometallurgical processing. The discarded products are manually dismantled into enclosures, motors, transformers, relays, circuit boards, cables, picture tubes, and other components; they are sorted into reusable components (transformers, memory chips, tantalum capacitors, etc.), reclaimable substance groups (noble metals, nonferrous metals, glass), and pollutant contents (PCB- containing capacitors, mercury/cadmium- containing primary and storage batteries). Recycling processes for circuit boards are presented in the form of a Sankey diagram in Figure 73 [242]. Mechanical grinding of the several sorted fractions follows in hammer mills, rotary knife cutters, or ball mills; the discharge particle size is such as to permit separation or reprocessing of the substances. Substances are separated according to their physical properties: by magnetic separation, eddy-current separation, dense-medium separation, and air classification. The resulting copper, aluminum, and iron fractions can be forwarded to appropriate industrial refiners or smelters.

Components that contain noble metals (circuit boards, contacts, etc.) are processed separately. To embrittle plastics for better grinding, the boards are sometimes heated to 425 °C. Hammer milling, especially for ceramic substrates, is followed by particle-size reduction in a ball mill. Without separation of nonmetallic and metallic substances, which is associated with losses of noble metals, the material obtained is forwarded to a copper or nickel smelter for further processing.

Hydrometallurgical processes must be considered for small operations where quicker recovery of noble metals is desired. Gold films can be removed from various substrates (along with copper, silver, and platinum group metals) by leaching with sodium cyanide and an oxidizing agent at room temperature. Gold, copper, silver, and the platinum metals are cemented with zinc, and the cementate is washed, dewatered, and melted in an induction furnace. The solution is regenerated and reused. The product metal contains 60 – 85 % gold, and the recovery rate is over 99 % [241].

Dissolution of metals from circuit boards with peroxodisulfates also decomposes pollutants such as polybrominated diphenyl ether flame retardants. Peroxodisulfates have an oxidation potential (+2.06 V) comparable with that of ozone. As Figure 74 shows for the example of copper, they can be anodically regenerated by electrolytic depletion of metals and returned to the circuit [243].

In a pyrometallurgical process, plastics are removed from the mechanically processed circuit boards removed by pyrolysis and the gas is combusted with an excess of oxygen. The solid residue can be melted and forwarded to a copper smelter for refining, or directly processed. The dust or sludge separated from the off-gas contains not only tin and lead but also noble metals, and must be subjected to further processing [241]. The solid residue, if directly processed in the recycling plant, must not contain any organic carbon, which would lead to excessively viscous slags in the arc or plasma furnace. A fluid slag is necessary for pyrometallurgical enrichment of noble metals in the metal phase. The slag system chosen depends on whether iron or copper is used as the metal collector. The slag system for iron is $CaO - SiO_2 - Al_2O_3$ and for copper, $FeO - SiO_2 - CaO$. If copper is used as

Figure 73. Sankey diagram for recycling of printed circuit boards [242]

collector, the process can be carried at 1350 °C and the noble metal containing copper can be cast into anodes. The noble metals accumulate in the anode slime during electrolytic refinement and are recovered by standard methods. The system with iron as collector requires temperatures 200 °C higher, and the iron must be slagged to enrich the noble metals by oxidation. The remaining iron is removed by treatment with hydrochloric or sulfuric acid after grinding. The advantage of iron over copper as a collector lies in the much better distribution of noble metals between metal and slag and thus in the higher degree of recovery [241].

Figure 74. Block diagram of metal reclamation with peroxodisulfate for the example of copper [243]

Another route for circuit board processing has been proposed by Norddeutsche Affinerie. Mechanical and thermal treatment is omitted; the boards are fed directly to the copper converter. Metals such as copper, nickel, and the noble metals are collected in the copper matrix and refined by conventional means. Organics burn off, and ceramic constituents report to a slag. Conditions in the converter and the downstream off-gas cleaning system are such that the sum of the toxicity equivalents of dioxins is < 0.1 ng/cm^3 [240].

7.5.4.2. Material-Specific Recycling

Material-specific recycling (Fig. 69, box 8) is characterized by remelting of scrap metals to obtain well-defined materials. Metallurgical operations are not involved. Deficient alloying elements can be supplemented. The prerequisites for material recycling are that the waste materials be isolated and that their exact composition and metallic contents be known. Waste metals to be melted together must exhibit compatibility and must be free from interfering substances.

Wastes are isolated by a discrete disassembly or by continuous size reduction. The extent of disassembly or grinding must be such that the parts of the waste product can be assigned to a definite waste class. If the composition of the wastes is not known, they must be analyzed before processing. Single analyses are laborious and can only be justified for large parts; therefore, methods have been devised for automatically identifying and sorting material in small pieces, such as those produced by shredders. These techniques are based on spark spectroscopy [244], [245] and/or X-ray spectroscopy [245–247]. Once identified, the particles are removed from the belt into the proper container either pneumatically or mechanically. For 15 – 65 mm particles, identification and sorting can be performed at up to 5 t/h with a discrimination $> 96\,\%$. Sorting by chemical composition may be preceded by sorting based on physical properties (magnetic, eddy- current, dense-media, or other separation methods) so that the resulting substance classes, such as ferrous metals, aluminum and aluminum alloys, copper and copper alloys, can be further sorted on the basis of chemical composition. Similar results can be achieved by replacing the combination of physical and chemical sorting by a multistage chemical method.

A waste class is characterized by the fact that a construction material can be obtained from it by melting without addition of primary metal. The materials belonging to such a class are said to be compatible, meaning that none of them has contents of alloying elements and impurities that exceed the maximum value for the construction material to be produced by melting. For example, the waste class AlMg includes the materials Al99.9Mg1, AlMg1, AlMg2.5, and AlMg3. Compatibility is also given if a construction material can be obtained from the wastes of several waste classes by melting without addition of primary metal. This is possible when alloying element or impurity contents exceeding the maximum values in one waste class are offset by lower contents in another waste class. The technique of "charge calculation" makes it possible to determine the optimal proportions of given wastes for producing a specified material of construction by melting to be calculated [248]. The question of compatibility also

arises with surface- coated wastes. A distinction must be made between coatings that dissolve in the melt, those that enter the slag, and those that are transported into the gas phase. The distribution of coating material between melt, slag, and gas phase depends on temperature and pressure, oxygen potential, and charging method.

7.5.4.2.1. Steel

World output of steel in 1990 was 770×10^6 t; 15 % was made in Siemens – Martin furnaces, 28 % in electric-arc furnaces, and 57 % in converting mills [249].

On average, making 1 t of steel required some 400 kg of scrap, 720 kg of pig iron, and 12 kg of iron sponge. Of the scrap used, 50 % goes to the electric-arc furnace, 20 % to Siemens – Martin furnaces, and 30 % to oxygen converters [250]. Scrap reprocessing began when Martin used plant scrap in 1865. The adoption of continuous casting, which accounted for 92 % of steel produced in 1991, resulted in a drop in plant scrap from 250 to 105 kg/t of crude steel in the output in Germany between 1960 and 1991 [251]. Total scrap iron production in Germany was ca. 20×10^6 t in 1989; 11 % of this was plant scrap in foundries, and 34 % was plant scrap steel mills and rolling mills [252]. In the same period, ca. 1.1×10^6 t of scrap iron was discarded with household waste, of which 564 000 t was recycled. This reclaimed scrap contained 275 000 t of tinplate scrap, over 50 % of which was recycled for tinplate packagings [253]. In all, 12×10^6 t of scrap, including 4×10^6 t of plant scrap was used in the production of 40×10^6 t of crude steel [254]. The scrap is used as a coolant in the oxygen converter and for the same purpose in ladle metallurgy. Simple scrap remelting is carried out in foundries. Up to 30 % scrap is used in converter steel mills; in Germany, 177 kg of scrap is used in making 1 t of crude steel (102 kg of plant scrap and 75 kg of external scrap) [251].

The electric-arc furnace can handle up to 100 % scrap. The Siemens – Martin process is no longer practiced in Germany. The recycling rate for ferrous metals in 1990 was 32 % in Western Europe and 70 % in Japan. If the fraction in Western Europe were also brought up to 70 %, steel output by the classical blast furnace/converter process would fall from 95×10^6 t to 52×10^6 t, while the share of the electric-arc furnace would rise from 45×10^6 to 88×10^6 t [249].

More than two-thirds of external scrap in Germany is inlet to the arc furnace, accounting for 17 % of steel output [251]. The electric steelmaking plant generates 13.3 kg of dust per tonne of crude steel. If this dust contains > 24 % zinc, it can be refined in nonferrous metal smelters. This is not a problem for electric furnaces, but the basic oxygen furnace puts out dusts with only 2 – 3 % zinc and 0.3 % lead [254]. In 1989, the total amount of strip and sheet coated in Germany was 3.8×10^6 t; 77.1 % received metallic coatings (57.1 % galvanized, 17.3 % tinplated). With regard to melting of the resulting wastes, it was assumed that lead and zinc vaporize and thus dissolve in the steel, aluminum reports to the slag, and virtually all copper and tin present are dissolved in the steel (Section 7.5.4.1.1). Tests yielded the following average values for the percentages of these elements dissolved in the steel: for the arc furnace, 88 % of copper and 58 % of tin; for the converter, 92 % of copper and 58 % of tin; in the crucible-type induction furnace, 24 % of lead, 19 % of zinc, 97 % of copper, and 93 % of tin. Lead and zinc levels could not be determined in either the arc furnace or the converter, but it can be assumed that the contents of lead and zinc in the steel will be much lower than in the crucible induction furnace because of the high temperatures [254]. Copper and tin levels in the steel must be kept low because even low levels of copper allow the steel to become brittle, especially when it is subjected to hot stress in forming [255]. Detinning of tinplate scrap may be necessary, particularly if the target recycling rate of 70 % is reached.

7.5.4.2.2. Aluminum

German aluminum output in 1988 was 1 275 000 t, of which 744 000 t was from primary production and 530 700 t from secondary production. Total consumption in the same period was 1 672 000 t of aluminum [256]. Figure 75 shows the principal mass streams and processes used to make 1000 kg of secondary aluminum in the Federal Republic of Germany in 1988. Steps upstream of the salt-bath furnace are furnace roasting or melting (depending on

the feed material), mechanical size reduction, physical sorting, and compression if appropriate. In Germany, aluminum scrap is melted almost exclusively in rotary drum furnaces under a salt cover consisting of ca. 70 % NaCl and 30 % KCl with addition of CaF_2. The salt slag protects the aluminum against oxidation and absorbs impurities as well as decomposition and oxidation products. This process generates 0.5 – 0.7 t salt slag per tonne of secondary aluminum; the salt slag is reprocessed (see Section 7.5.5). Cast alloys are produced from wrought alloys with loss of magnesium. The amount of recycled scrap in Germany, however, has already surpassed cast alloy production, so that wrought alloys are increasingly being made into new wrought alloys. These wrought alloys contain magnesium, manganese, and silicon as principal alloy constituents; some additionally have zinc or copper. The sum of all alloying elements is around 2 – 2.5 %. The main alloying elements in cast alloys are silicon, copper, and magnesium, making up some 12 % in all [248].

Some aluminum scrap is painted or has other organic coatings. This scrap cannot be fed directly to the rotary drum furnace; the coatings must be removed by roasting. The problem is that this process takes place very slowly at low temperatures and yields inconsistent results. At high temperatures, however, there is the risk of oxidizing the aluminum. In the United Kingdom, a fluidized-bed rotary furnace has been developed for removing paint, plastics, and other combustible materials from aluminum. The heated fluidized bed consists of an inert material such as Al_2O_3. The gas produced is burned in a final combustion chamber. Gränges in Sweden employs a two- chamber furnace in which the organic components in the scrap are roasted in the first chamber, and the roasting gases are burned in the second. The energy consumption for roasting and melting is partly covered by the roasting gases [257]. On the basis of a U.S. patent, Vereinigte Aluminiumwerke (VAW) has devised a three- chamber furnace for processing painted, coated, and oil- contaminated materials. Melting capacity is 3 t/h; the furnace holds 90 t, of which 70 t is left in the unit to ensure that the passages between chambers remain below the bath surface so as to separate the different gas atmospheres in the chambers. This furnace is run as a system isolated from the outside atmosphere. The energy content of the roasting gases is used for the system, and the heat content of the flue gases is recovered and utilized to preheat the combustion air. Oxidation of the aluminum is prevented by not allowing the scrap to come in contact with any flame. Energy is supplied in the main hearth, not the melting hearth [253].

7.5.4.3. Recycling of Material Wastes

Metal waste (scrap waste) that is not subject to material-specific recycling is inlet to the third variant of product waste recycling, namely recycling of material wastes (Fig. 69, box 10). Part of this stream may originate in product-specific recycling. The cost per unit of metal reclaimed is higher in this variant than in product-specific or material-specific recycling. Recycling of material wastes is characterized by metallurgical removal and separation of substances.

Aluminum is a relatively base metal, and so only a few elements can be removed from molten aluminum by refining. Aluminum scrap is therefore selected to have compatibility for material-specific recycling, so that the desired construction material can be obtained without refining, apart from the removal of a few impurities. In contrast to aluminum, copper is a relatively noble metal and can readily be separated metallurgically from other elements. Copper and copper alloy scrap from which construction materials can not be made by direct remelting is forwarded to recycling of material wastes.

World copper consumption in the year 1991 was 12.18×10^6 t. Of this, 38.3 % was produced from secondary raw materials. In Germany, 1989 consumption was 1.128×10^6 t of copper, 553 000 t (49 %) of which was made from copper- containing scrap [221], [233]. Copper wastes can consist of copper compounds (mostly oxides) or be metallic. Metallic copper wastes are classified as copper scrap generally containing more than 96 % copper, copper alloys (bronze, red and yellow brass, nickel silver, etc.), and copper composites (radiators, motors, armatures, etc.). These wastes are subjected to a variety of metallurgical operations, depending on their compositions.

Figure 76 presents the flowsheet of Hüttenwerke Kaiser [222], [233]. Most of the copper is reclaimed by pyrometallurgy. The

Figure 75. Material streams for production of 1000 kg of secondary aluminum [256]

main processes are reduction and refining. Operations such as cementation and reductive electrolysis are not important in the recycling of copper. Shaft furnaces, electric furnaces, and top-blown rotary converters (TBRC) are employed for reduction; both stationary and tiltable reverberatory hearth furnaces as well as rotary drum furnaces are used in refining. Feeds to shaft furnaces range from low-copper dusts, ashes, and other fine-grained materials and nonmetallic residues to shredder material and copper – iron materials, and also include various slags and residues from other copper-enrichment processes. Shaft furnace feeds are divided into tin-rich and zinc-rich materials. The shaft furnace, like the blast furnace, operates in a countercurrent fashion: Alternate portions of coke and burden are supplied from the top while air is injected through tuyeres at the bottom to effect combustion of the coke and generate the proper furnace atmosphere. In contrast to the blast furnace, the shaft furnace has a "fire top" to oxidize vapors of tin, lead, and especially zinc in the furnace. These oxides then pass to the off-gas filtration system. The metal phase forms in the lower furnace; depending on the burden, it contains ca. 70 % copper along with tin, lead, zinc, nickel, and iron. A $CaO - SiO_2 - FeO$ slag is also pro-duced. Metal and slag can be tapped at around 1300 °C, either continuously or intermittently. Metals produced in the shaft furnace with zinc-rich burden contain over 80 % copper; these, unlike tin- and lead-rich metal, can be forwarded directly to the anode furnace for preliminary refining. Both kinds of shaft fur-

Figure 76. Block diagram of a secondary copper smelter [222]

nace produce an inert slag, which is salable as a building material.

The top-blown rotary converter can be used for the same operation as the shaft furnace. The TBRC always operates in batch mode. The charge is melted by a torch fed with gas, fuel oil, and also powdered fuels. The metallurgical process is similar to that in the shaft furnace, but mass transport is much more intensive because of the rotation and the blowing of combustion gases onto the melt. The fuel/air ratio in the TBRC can be used to set up a reducing atmosphere, as in the shaft furnace, or an oxidizing atmosphere, as in the converter. This equipment is thus more flexible than the shaft furnace [222].

The original Knudsen patent application on the conventional scrap-metal converter for refining copper alloy scrap was filed as early as 1915. In the converter, a horizontal cylinder with tuyeres on the sides, coke is burned to melt the copper alloy scrap (yellow and red brass, bronze, etc.) together with tin- and lead-rich copper from the shaft furnace. When air is blown through the melt, some of the inlet tin, lead, and zinc is volatilized, and is recovered as flue dust in the filter. At the end of the charge, a metal containing ca. 96 % copper, some of the inlet nickel, and the noble metals is left in the converter. This metal is forwarded to the anode furnace for rerefining. In addition to iron, the slag contains part of the inlet valuable metals and is therefore returned to the shaft furnace. The mixed tin-, lead-, and zinc- containing oxides from the shaft kiln and converter are fed to the reverberatory furnace or rotary reverberatory furnace, where they are melted under reducing conditions with soda and coal fines; the zinc is volatilized and is then oxidized to zinc oxide. The lead – tin alloy is used as a starting product for soldering tin, type metal, and other metals. The zinc oxide can be sold as a paint pigment. The zinc oxide from the shaft kiln is less pure and is therefore delivered to a zinc smelter for zinc recovery [258], [259].

Copper from the converter and the shaft kiln for zinc-rich material are melted together with copper scrap containing over 96 % copper in the anode furnace (stationary or rotary reverberatory furnace) and refined. Refining is effected by blowing in air; the next step is reduction by poling with tree trunks or injecting natural gas. Of metallic impurities, aluminum, zinc, and iron can be decreased to < 0.01 %, lead and tin to ca. 0.2 %. Nickel and noble metals, in contrast, virtually cannot be removed by pyrometallurgy. The metal produced in this way, with about 99 % copper, is cast into anodes for electrolytic refining.

In this electrolysis, the anodes are dissolved in sulfate electrolytes when a d.c. voltage is applied. The baser elements, such as nickel, arsenic, zinc, and iron, go into solution in ionic form along with copper or are, like lead, precipitated as sparingly soluble compounds. Elements more noble than copper are not dissolved. Noble metals such as silver, gold, and platinum group metals accumulate in the anode slime with the sparingly soluble compounds. The noble metals, present at very low concentrations in the feed, are enriched to 7.5 % in the anode slime [233]. Apart from the noble metals, tin, antimony, arsenic, selenium, and tellurium are recovered from the anode slime. In principle, only copper is deposited on the cathode in a purity of at least 99.95 %. The secondary copper obtained in this way is of a quality equivalent to copper derived from primary resources. The impurities accumulating in the electrolytes are removed by electrolyte conditioning. In producing 116 000 t of cathodic copper from secondary raw materials, Hüttenwerke Kaiser obtained 2300 t/a of nickel sulfate and 2800 t/a of copper sulfate by fractional crystallization and electrolytic copper recovery from electrolytes. The sulfate removed in these operations must be made up by adding 78 % sulfuric acid to the electrolytes [222], [233].

The cathodes are then melted in the wire bar furnace and the copper is either cast into wire bars or continuously cast into long formats.

7.5.5. Recycling of Residues

In residue recycling (Fig. 69, box 12), nonmetallic wastes obtained in various other forms of recycling are used to produce metals. Residues from production are treated by production waste recycling (box 2). The methods used to treat production residues are similar to those for recycling residues, but the two types of residues usually differ in that recycling residues are more contaminated and/or intermingled. The effort and costs for obtaining metals of a given purity are greater for recycling of recycling residues than for recycling of production wastes. Residue recycling deals only with residues from recycling.

Electric Arc Furnace Fly Ash. About one-third of the zinc consumed in the Federal Republic of Germany in 1987 was used for surface coatings [260]; this corresponds to 2.8×10^6 t of steel (strip and sheet) receiving zinc coatings. In the United States and Western Europe, the processing of galvanized sheet steel in the electric arc furnace leads to zinc- and lead-containing dusts, each in a quantity of 500 000 t/a [220]. Of this dust, ca. 880 000 t, containing $> 150\,000$ t of zinc was recycled in the Western world [261].

The rotary-furnace volatilizing process (Waelz kiln) was established for processing electric steelmaking plant dusts with 10 – 35 % zinc and 3 – 6 % lead. This process features continuous operation in an inclined rotary furnace, the use of solid reducing agents, and the avoidance of liquefaction of the furnace contents. Zinc-containing feed materials are reduced by the added carbonaceous materials; the resulting zinc vapor is reoxidized in the furnace and carried out with the flue gas as ZnO. Lead is volatilized in the metal form and also in the sulfide form, the oxide, or the chloride. The product oxide, containing 54 – 58 % zinc and 8 – 12 % lead, is forwarded to zinc smelting. The slag, with an FeO content of 34 – 38 %, can be used for roadbuilding and as construction material. Before being delivered to the Imperial Smelting (IS) process or the lead – zinc blast furnace, the oxides produced are agglomerated. Hot briqueting (Fig. 77) has been used for this purpose by Berzelius since 1975. Virtually all the oxides in the feed material can be briqueted at ca. 500 °C without added binders [219]. The briquetts are charged together with lumpy sinter of primary raw materials at 200 °C, coke preheated to 800 °C, and small amounts of lime as a slag-forming agent. The air needed to com-

bust the reducing agent is preheated to 1150 °C. After reduction in the shaft, lead bullion and slag are tapped at the hearth of the furnace. The top gas discharged from the furnace at about 1000 °C contains ca. 6 – 8 vol % zinc vapor, 10 – 12 vol % CO_2, and ca. 20 vol % CO. The zinc vapor is condensed to liquid in a lead-spray condenser at the head of the furnace and is withdrawn continuously. The zinc dissolved in the hot lead in the condenser is separated from the lead melt in the cooling trough and at lower temperature in the softening furnace; the lead is returned to the condenser. The resulting crude zinc contains 98 % Zn [262]. In addition to flue dusts from electric steelmaking plants, a wide variety of other zinc- containing residues can be handled in the IS blast furnace (Fig. 77).

Salt Slags. Virtually all the 530 000 t of secondary aluminum produced in Germany in 1988 came from rotary drum furnaces. For each tonne of secondary aluminum, between 0.5 and 0.7 t of salt slag was also produced, depending on the degree of contamination of the feed aluminum scrap. The resulting output of salt slag was ca. 270 000 t. In addition some 75 000 t of widely varying drosses and dusts occurred in ball mills, generated by conditioning of aluminum drosses [263]. About 600 000 t of salt slag was produced in Western Europe in 1990 [220].

Today this salt slag is treated by the B.U.S.-Chemie solution- crystallization process. The steps in this process are crushing, screening, and dry separation of aluminum metal; dissolving, degassing, and preparation of a solid-liquid suspension; separation of off-gases, thickening, filtration of insoluble matter, recovery of alumina; and crystallization, centrifugation, and recovery of recycling salt. On the basis of an average salt/slag ratio of 600 kg per tonne of secondary aluminum, this means that on average the conditioning of salt slag corresponding to 1000 kg of secondary aluminum yields 42 kg of aluminum alloy pellets, which can be directly forwarded to remelting plants; 167 kg of recycling salt, which can be used as cover salt in rotary drum furnaces; and 196 kg of alumina residue containing heavy metals in a nearly insoluble form, which can be disposed of in landfills. The gases evolved on dissolution (relative to 1000 kg of secondary aluminum produced) contain 4.5 cm^3 H_2, 2.0 cm^3 CH_4, 0.31 cm^3 NH_3, 0.02 cm^3 PH_3, and 0.0001 cm^3 H_2S. The gases are treated with activated carbon; PH_3 and H_2S are adsorbed on the carbon, contacted with diluting air, and thus oxidized so that the treated gas is in compliance with emission limits [263], [264].

7.6. Sludges

7.6.1. General

Sludges vary widely in character and are treated or disposed of for a variety of purposes. As a consequence, sludge treatment imposes stringent requirements on the physical, chemical, and biological processes involved: transformation of matter, solid – liquid separation, and thermal treatment. Associated with these basic operations are the secondary problems of controlling liquid and gaseous emissions.

The bulk of sludges comprises sewage sludges, industrial production sludges, water treatment sludges, dredging sludges, and mining sludges.

Because treatment of sewage sludge is by far the most serious problem today, the discussion that follows is concerned with this topic; the other types of sludge and problems relevant to them are mentioned only in passing.

Most of the techniques used for sewage sludge treatment can be employed in identical or modified form for other sludges.

The treatment of slurries and sludges in production processes must be optimized with regard to process and product quality, and most known process sequences go through a long development period before they are perfected. When sludges are disposed of, legislation and regulations governing the returning of sludge components to the environment must be borne in mind. Legislative and regulatory provisions can lead to technical guidelines that bar the use of proven techniques and mandate conversion to new processes.

7.6.2. Quantities of Sewage Sludge Treated

The amount of sludge produced depends on the effectiveness of wastewater treatment. A definite quantity of sludge can be anticipated for a given treatment method.

Figure 77. Processing of steel-mill dusts and other Zn- and Pb- containing secondary materials together with primary raw materials [219], [262]

Advanced wastewater treatment practices, in particular nitrification/denitrification and precipitation of phosphates, are expected to result in appreciable changes in both the specific quality and the volume and mass flow rates of sewage sludges.

The precise extent of these changes in per capita sludge solids and sludge volume cannot be statistically calculated today because not enough representative data have been collected.

It is, however, clear that the increase in amount of solids and the increase in volume are not synchronized. In phosphate precipitation especially, the choice of process and of precipitating agent have a substantial effect on the per capita quantities.

With regard to nitrification/denitrification, no significant increase in sludge solids is anticipated; there may in fact be a reduction of up to 10 % in the per capita quantity of sludge solids. The per capita liquid sludge volume is likely to rise by 10 – 20 %, however.

With the simultaneous precipitation of phosphates as now favored, a 20 % increase in the per capita amount of sludge solids can be expected.

The rise in per capita volume depends on the type of biological treatment process and the precipitating agent used; on the whole, an average rise of ca. 10 % range can be anticipated. In general, it can be assumed that the use of upstream or downstream precipitation tanks instead of simultaneous precipitation will result in markedly greater increases in the per capita solids quantity and sludge volume.

If the two advanced wastewater treatment processes are combined, the percentage rise in per capita sludge volume will be greater than the percentage increase in sludge solids per person.

A rough figure for the quantity of sewage sludge generated per person (or person-equivalent) per day is 2 L, with a solids content of ca. 4 %.

Calculations of sludge quantities have to take account of project-specific features having to do with the sewer system type (combined or separate) and the character and size of industrial users.

At present, the quantity of sewage sludge to be treated in Germany is ca. $(65 - 78) \times 10^6$ m^3/a,

with an average solids content in the range of 4.2 – 4.6 %.

7.6.3. Requirements for Sludge Recycling and Disposal

The ultimate goal of sewage sludge treatment is reclamation or disposal of residues contained in the sludge.

The dominant disposal options at present are agricultural use and landfill disposal after mechanical dewatering.

German legislation sets some rules for these general reclamation/disposal approaches.

The modalities of the Sewage Sludge Regulation (Klärschlammverordnung) [265] govern the agricultural use of sewage sludge.

The most important limits set by this regulation apply to the content of heavy metals in sludges approved for agricultural use and in the soils to which they are applied (see Table 14).

Table 14. Heavy metal limits in sewage sludges and soils when sewage sludge is used agriculturally in accordance with German sewage sludge regulations

Metal	Concentration in sewage sludge, mg/kg∗	Concentration in soil, mg/kg soil
Lead	900	100
Cadmium	10/5∗	1.5/1∗
Chromium	900	100
Copper	800	60
Nickel	200	50
Mercury	8	1
Zinc	2500/2000∗	200/150∗

∗ Dry matter. ∗∗ For application to light soils with < 5 % clay and soils with pH between 5 and 6.

The deposition of sewage sludges in landfills of various categories is subject to the criteria of the Technical Directive on Municipal Waste [266] (see Table 15).

The limitation on organic content in dry sludge, determined as loss on ignition, means in practice that sludges cannot be placed in landfills without incineration as a treatment step.

In a transition period extending until the year 2005, the method of sewage sludge disposal that is by far most commonly practiced now – landfill disposal after mechanical dewatering – will continue to be permitted. Local landfill operators, however, are requiring improved strength values for sludges to be disposed of (see Table 15).

7.6.4. Sewage Sludge Treatment Processes

The purpose of sewage sludge treatment is to prepare raw sludges differing in origin and composition for reuse or ultimate disposal. A number of processes and combinations of processes have been developed.

The most important combinations now used in industrialized countries are summarized in Figure 78 [267].

Once the quality requirements of the Technical Directive on Municipal Waste come into full force, the combinations numbered 6, 7, 13, 14, 19, and 20 will be removed from the list.

7.6.5. Unit Operations in Sewage Sludge Treatment

7.6.5.1. Thickening and Dewatering

Sewage sludges have water contents of ca. 90 – 99.5 % depending on origin. The high water contents and the resulting large sludge volumes cause problems in some sludge treatment processes. In addition, many sludges have a high water-retention capacity, arising from various kinds of binding force, which makes the removal of water difficult.

The most important unit operations in sewage sludge treatment thus include thickening and dewatering.

Sludge thickening can be performed with the aid of gravity or by centrifugation. This removes chiefly interstitial water, which is retained only by weak forces. Thickening of sewage sludges can also be effected by flotation or with filters.

Higher pressure differences (positive pressure or vacuum) in mechanical dewatering or more intensive centrifugation can overcome the stronger forces binding contact and capillary moisture to the solids. Figure 79 shows how the technologically and economically optimum volume reduction can be achieved by removal of sludge water in these types of equipment and in the thermal processes of drying and incineration.

The thickenability and maximum dewaterability of sewage sludge are listed in Table 16. Table 17 presents attainable results in

Table 15. Landfill classification criteria according to the Technical Directive on Municipal Waste, Annex B

Number	Parameter	Criterion values	
		Landfill class I	Landfill class II
1	Consistency [a]

4.20	Water-soluble fraction (residue on evaporation)	$\leq$ 3 wt %	$\leq$ 6 wt %

[a] 1.02 together with 1.03 can be used as equivalent to 1.01. The consistency must be determined for each case in accordance with statistical requirements for landfill stability. 1.02 combined with 1.03 represents a lower boundary especially for cohesive, fine-grained wastes.
[b] 2.01 can be used as equivalent to 2.02. Requirement does not apply to contaminated soil that has been excavated and is to be placed in a hazardous-waste landfill.
[c] Limit may be exceeded up to 1 400 mg/L SO_4^{2-} for gypsum rubble and gypsum construction waste as well as other gypsum-containing building rubble, provided the Ca^{2+} concentration in the eluate is at least 0.43 times the SO_4^{2-} concentration.

Table 16. Thickenability and dewaterability of sewage sludge (in % solids content) [258]

Water-retaining properties of sludge	Thickenability[a]	Dewaterability		
		Continuous belt filter,[b] and centrifuges[c] polymer conditioning	Filter-presses, metal salt or polymer conditioning	
			with lime/additives	without lime/additives
Good thickenability/dewaterability	>7	>30	>38	>45
Moderate thickenability/dewaterability	4 – 7	18 – 30	28 – 38	35 – 45
Poor thickenability/dewaterability	<4	<22	<28	30 – 35[c]

[a] Static thickening without conditioning. [b] For initial solids content 3 – 9 %. [c] Higher values can be obtained with high-performance centrifuges.

Figure 78. Possible combinations of processes for treatment, recycling, and disposal of sewage sludges

mechanical dewatering of sewage sludge when various conditioning methods are employed.

For detailed discussion of these topics, see [268].

7.6.5.2. Stabilization

DIN 4045 defines the stabilization of sludges, especially sewage sludges, as methods of sludge treatment for the purposes of:

1) Decreasing the amount of odor-forming constituents
2) Reducing the quantity of sludge solids
3) Improving dewaterability
4) Diminishing the number of pathogens

The following are distinguished:

1) Aerobically stabilized sludge
2) Anaerobically stabilized or digested sludge
3) Chemically stabilized sludge
4) Thermally stabilized sludge

The purpose of stabilizing sewage sludges is to reduce the content or modify the character of organic substances that can be attacked by putrefactive bacteria in such a way that the sludges so treated have no further appreciable noxious and polluting effects or impacts on the environment. Generally, the degradation and transformation processes associated with stabilization involve transformation of high-molecular mass sludge constituents to lower molecular mass compounds. Often the aim is mineralization, that is, their transformation to inert species. Of the possible processes for sludge stabilization, the biological methods of aerobic and anaerobic stabilization have gained the widest adoption.

One method of chemical stabilization is to add substances (chiefly lime) that raise the pH drastically, thus hindering transformation processes. This method is mainly used in the Scandinavian countries.

Figure 79. Technically and economically optimal volume reduction by dewatering and incineration or combustion

Formally, all thermal treatments are classified as chemical processes; these include combustion/incineration, wet oxidation, and gasification (see Sections 9.3 and 9.4).

Aerobic biological stabilization of sewage sludge has the following variants:

1) Simultaneous aerobic sludge stabilization
2) Separate aerobic sludge stabilization at ambient temperature
3) Aerobic-thermophilic sludge stabilization in the liquid phase
4) Aerobic-thermophilic sludge stabilization in the solid (or nonflowable) state of aggregation (sludge composting)

For a discussion of the principles underlying these methods, see [269].

The dominant biological process in larger treatment systems is anaerobic digestion. The microbial transformations are effected by groups of bacteria that function under air exclusion at 30 – 55 °C.

This process yields biogas, which can be used to generate energy.

Aerobic processes and digestion can be combined in so-called dual sludge stabilization. The combination of an upstream aerobic-thermophilic stage and a downstream anaerobic stage operating in the mesophilic temperature range is most widely used.

Table 17. Mechanical sludge dewatering as a function of conditioning process, under the assumption of moderate sludge dewaterability [258]

Conditioning process	Centrifuges∗ and continuous belt filter				Filter presses			
	Dry residue,∗∗ %		Laboratory transverse resistance, kN/m^2		Dry residue,∗∗ %		Laboratory transverse resistance, kN/m^2	
	Mean	Range	Mean	Range	Mean	Range	Mean	Range
Conditioning with polymers	25	18 – 30	3	1 – 5	32	28 – 38	15	8 – 30
Conditioning with metal salts	Not usual for municipal sewage sludge							
Conditioning with metal salts and slaked lime	not appropriate				40	35 – 45	25	10 – 100
Thermal conditioning	Not recommended due to secondary pollution							
Condtioning with polymers and powdered coal	Only appropriate with subsequent incineration							
Conditioning with polymers and pre- or post-treatment with quicklime, cement/fly ash	depends on disposal objective and quantity		10	3 – 30	rarely used			
Conditioning with polymers and post-treatment with ballasts	depends on disposal objective and quantity		3	1 – 5	not appropriate			

∗ Higher values can be obtained with high-performance centrifuges.
∗∗ Including conditioning agents and additives.

Figure 80 shows graphically the recommended application areas of the main biological stabilization processes with respect to plant size. Further information on dual biological stabilization can be found in [270].

7.6.5.3. Disinfection

The German Sewage Sludge Regulation no longer mandates the disinfection of sewage sludge prior to distribution on certain types of agricultural land. It is, nevertheless, a quality-enhancing practice in sludge recycling, and purchasers and users in the agricultural sector place a positive value on it.

The processes most suitable for disinfection of sewage sludge are those in which the temperature reaches the thermophilic range ($> 55\,^{\circ}$C).

These include aerobic – thermophilic stabilization in the liquid or solid state (composting). An hygienic product can also be obtained by thermophilic digestion or dual sludge stabilization.

Process conditions for proper disinfection are discussed in [271].

7.6.5.4. Conditioning

The purpose of sludge conditioning is to improve sludge thickenability or dewaterability. Sludge conditioning can be effected chemically or physically.

In chemical conditioning, coagulation and flocculation are induced or accelerated in several ways. An organic flocculant can be added to promote solid – liquid separation, or an inorganic flocculant or precipitating agent can be used to form flocs under hydrolyzing conditions. The modification or neutralization of the electrostatic charges on the sludge constituents or the creation of new chemical compounds also leads to the formation of microflocs on the solid and colloidal particles present in the sludge.

The multiplication of solid particles leads to larger agglomerates /microflocs. Because the water-retaining capacity is simultaneously reduced, sedimentation is accelerated and filterability is improved.

Physical conditioning processes fall into mechanical and thermal classes. Mechanical conditioning changes the structure of the constituents in the sludge by the addition of in-

Figure 80. Recommended application ranges of principal variants of biological sewage sludge stabilization in relation to treatment plant size

organic or organic reagents that do not initiate chemical reactions. Effective additives include ash, coal dust, sawdust, sand, and infusorial earth products. In thermal conditioning, the same above mechanisms are effected by freezing or heating the sludge.

Low-temperature conditioning involves lowering the temperature to – 20 °C. This technique is used primarily in regions with a cold climate and is commonly practiced in natural (gravity) dewatering units.

Thermal conditioning methods are classified by temperature range. Low-thermal conditioning takes place between 60 and 80 °C. High-thermal conditioning is carried out between 180 and 230 °C at 10 – 25 bar. The use of thermal conditioning has declined greatly, since the process gives rise to intense odors (especially the high-temperature variant) that usually cannot be controlled.

Table 17 summarizes sludge dewatering as a function of the conditioning process.

7.6.5.5. Drying

If it is necessary to go beyond the degree of water removal given by mechanical dewatering and also remove ballast water, the only option is "thermal dewatering" or drying.

"Complete" drying makes it possible to increase the fraction of dry residue in the sludge to 90 %, sometimes over 95 %.

The extent of sludge drying and the method used will depend chiefly on the downstream sludge treatment steps or the mode of recycling or ultimate disposal. Processes fall into two major classes: convection drying and contact drying.

In convection dryers, heat is supplied by hot gases flowing through the sludge. In contact dryers, heat is delivered through heated wall surfaces. The control of emissions is a major problem in the drying of sewage sludges.

7.6.6. Quantities of Other Sludges;Disposal Options

7.6.6.1. Industrial Production Sludges

The discussion in the preceding sections includes sludges from industrial production that are generated either in special industrial treatment plants or in municipal treatment facilities into which industrial wastewaters are introduced.

In addition, production processes generate a variety of sludges that must be disposed of. Examples are hydroxide sludges, roll-sintering sludges and metal sludges from the iron and steel industry, sludges from food and sugar production, papermaking sludges, and so on.

The potential quantities of these can be determined only approximately, because in many cases the disposal of such sludges has never been regarded as a problem. The total quantity of these production sludges in Germany is estimated at $(40-50)\times10^6$ m^3/a. This quantity is associated with a dry residue of about 5 %. The sludges, primarily inorganic (e.g., hydroxide sludges), are mostly dewatered mechanically and disposed of in landfills.

Sludges with predominantly organic constituents may present serious problems in regulated disposal. Organic production sludges have properties comparable to those of municipal sewage sludges, but they are generally more voluminous and more difficult to dewater.

Sludges from metal-processing industries with high contents of heavy metals are regarded as hazardous waste. Much more problematical from the process engineering standpoint are many types of organic production sludges, because their dewatering or other required treatment is often difficult. In the case of fermentation residues, for example, conventional conditioning and dewatering processes rarely yield a sludge suitable for landfill disposal.

For a number of chiefly organic production sludges, the only available disposal method in the future will be thermal utilization after dewatering to a high solids content (and possibly drying). One example is sludges from papermaking. Sludges suitable for agricultural use, sometimes after intermediate composting, are chiefly those from food production. Dewatering is usually required here to lower transport costs.

7.6.6.2. Water Treatment Plant Sludges

Along with sludges from municipal sewage and industrial wastewater treatment plants, sludges generated in water treatment have begun to represent a disposal problem. In purely quantitative terms, these sludges have not yet become very significant.

Figure 82. Intermediate storage site for hazardous wastes in Frankfurt/Main
1) Street; 2) Track system; 3) Buried steel tank for contaminated fire fighting water; 4) Sidewalk; 5) A1 storage; 6) Drum storage 3; 7) Equipment stand; 8) Sludge pits; 9) Silt trap; 10) Gasoline separator; 11) Stands for skips; 12) Boot washing station; 13) Social services building; 14) Spare part storage; 15) Operations building; 16) Substation; 17) Gate; 18) Barrier; 19) Scale; 20) Sampling pit; 21) Incoming truck parking; 22) Storage for toxic substances and samples awaiting analysis; 23) Storage; 24) Office containers; 25) Railway track; 26) Physicochemical treatment; 27) Ramp; 28) Chemical transfer; 29) Hydrant 1; 30) Lime bunker; 31) Storage basin; 32) Scale, 3 t; 33) Transfer station; 34) Sand separator; 35) Bicycle racks; 36) Hydrant 2; 37) Drum storage for solid wastes for incineration, recycling, and landfilling; 38) Drum storage for PCBs, acids, alkalies, and neutrals; 39) Equipment storage

More than 80 % of such sludges go to landfill disposal at present. Because they contain only small amounts of organic substances, thermal processes are not relevant. In the future, disposal of sludges generated in water treatment is likely to be monitored more closely, and criteria applicable to them will be similar to those for sewage sludges.

7.6.6.3. Dredging Sludges

Sludges produced in the dredging of waters represent a major potential problem.

In total, 100×10^6 m^3 of sludge is dredged annually from German waterways, seaports, inland harbors, lakes, and smaller bodies of water. Of this amount, some $(25-35) \times 10^6$ m^3 is piled on land; the rest is dumped elsewhere in inland waters or at sea.

Dredging sludges contain on average 60–65 % dry residue at the time of production, though much lower figures are also possible depending on the sludge composition.

For simplicity, the dredged solids can be regarded as half sand, in various grain-size distributions, half fines, whereby this distribution can vary to a wide extent locally. The organic content of the fine fraction varies widely and can be as high as 60 %.

Pollutants in the dredged solids accumulate chiefly in the fines. The concentration depends on the burden of pollutants entering the body

of water in question, but also increases with decreasing flow velocity. In rivers and streams particularly, the content of heavy metals often exceeds the limits set forth in the German Sewage Sludge Regulation.

Figure 83. Intermediate storage site for hazardous wastes in Mitterteich
a) Operations building; b) Scale; c) Sampling pit; d) Storage tanks; e) Stands for skips; f) Semitrailer stands; g) Solids storage pile

Lakes have a significantly lower content of heavy metals, but the level of sapropel with its nitrogen compounds and phosphates as well as other oxygen-depleting substances is higher.

At inland sites in particular, the classical method of ponding is increasingly disallowed because it is no longer possible to find sufficiently large deposition areas near the shore, or because approval can no longer be obtained for a variety of reasons.

Even in coastal areas, drastic restrictions of this simple, cheap technology are becoming common.

Dredging sludges are commonly not considered for agricultural use because they often contain high levels of heavy metals and toxic organic compounds.

For the proper disposal and transportation of this material, it is necessary to dewater it to a high solids content and take account of the soil-mechanical aspects of landfill disposal.

The heavy-metal burden of dredged solids is largely associated with the fine fraction. If the coarse, sand fraction can be separated, the quantity of contaminated dredged material can be appreciably reduced.

The "traditional" method for separating sand from dredged solids is with the longitudinal-flow classifier, which exploits the difference in settling velocity of the sand and fines. The sand drops out in the fore part, near the inlet, while silt, clay, and organic substances pass on to the end, where the flow velocity declines so much that the fine particles can settle out. The main drawback to this method is the large area required.

Modern mechanical separation techniques are either still under testing or have been in full-scale use for only a few years. For example, after collection of coarse material in a hydrocyclone, the dredged solids can be divided into a sand and a fines fraction in a hydraulic classifier. The sand is washed and can be used as a building material. The mud goes to a centrifuge or other dewatering equipment, after which the solids can be disposed of.

The space requirement for such a processes is ca. 15 % of that for longitudinal-flow classification. Furthermore, the process can be run continuously, it is independent of weather, and there is virtually no seepage of contaminated water into the subsoil.

7.6.6.4. Sludges from Mining

Sludges originating from mining and quarrying generally exhibit good dewaterability and have a high solids content made up of granular particles. After dewatering, these sludges can be placed in landfills.

Restrictions may be applied in the future if the landfill criteria of the Technical Directive on Municipal Waste [266] cannot be formally complied with.

8. Intermediate Storage of Hazardous Wastes [272–275]

8.1. Introduction

Specially designed and equipped plants are required for the collection, intermediate storage,

processing, recycling, and disposal of hazardous wastes. These facilities must not only meet the requirements of relevant regulations and serve the ends of environmental protection but must also embody the state of the art.

For economic reasons, plants for the reutilization or disposal of wastes, such as incineration plants and landfills, are established on a supra-regional basis. It is therefore desirable, and sometimes also necessary, to erect intermediate storage sites, collecting points, and even small temporary storage facilities in order to ensure wide-area collection of hazardous wastes in accordance with industrial and commercial needs.

Figure 84. Intermediate storage facility for small quantities of hazardous wastes

8.2. Intermediate Storage Sites

An intermediate storage site is a fixed plant in which wastes are received, held in pretreated form, and collected for forwarding to disposal sites.

Generally, intermediate storage sites consist of several zones, with a fairly consistent layout and usually the same equipment. The standard setup includes buildings with the receiving department and laboratory, a truck scale, and storage facilities for solid, liquid, and pasty wastes.

The main tasks of intermediate storage facilities is to reduce the volume of organically and inorganically polluted wastewaters that are subjected to physicochemical treatment. The latter generates detoxified, neutralized, and dewatered residues for recycling or landfill disposal; organic material for combustion; and cleaned wastewaters that can be released to a sewage works or receiving water.

Another function of intermediate hazardous-waste storage sites is the collection of small amounts of waste from medium-sized and small industrial operations, service areas, and households.

Figures 81 and 82 show two large intermediate storage sites in Munich and Frankfurt/ Main, both with physicochemical treatment systems. A smaller facility without physicochemical treatment is illustrated in Figure 83. Figure 84 shows how an intermediate storage site for small quantities of hazardous waste can be set up.

8.3. Zone Structure of an Intermediate Storage Site

An intermediate storage facility consists of several zones. For small units without processing systems, a site of ca. 5000 m^2 is sufficient. Large intermediate storage sites with treatment systems, such as physicochemical processing, may require 10 000 – 20 000 m^2.

The storage facility can generally be described in terms of the following zones: 1) Entry zone, 2) Traffic zone, 3) Storage zones, 4) Processing zone.

Entry Zone. The following are located in the entry zone:

1) Operations building with receiving, laboratory, and social rooms
2) Multipurpose building with storage rooms and workshop
3) Truck scale with holding area for arriving trucks waiting to be weighed
4) Sampling station with self-contained drainage and roof
5) Storage for samples awaiting analysis

The size of the operations building with its social rooms is governed by the number of employees. A small intermediate storage site can be run with three to five persons; a large one with a processing system such as a physicochemical treatment system would need a staff of 25 – 30. The laboratory, usually located in the

operations building, should be able to cover plant requirements and perform the monitoring and supervisory functions mandated by regulatory agencies. A high-performance, well-equipped laboratory can be a significant cost factor in an intermediate storage site.

The multipurpose building usually houses the machine shop, electrical shop, spare parts and equipment storage rooms, and space for on-site vehicles such as forklifts, suction trucks, sweepers, etc.

The truck scale is usually an 18 m scale; large facilities have two of these. The scale can weigh a complete tractor-trailer rig. Standard equipment includes a calibrated 3 t scale for weighing small quantities delivered in drums and casks.

Arriving trucks are briefly stopped at the sampling station (sampling pits) so that samples can be taken. The sampling pits have a self-contained drainage system and are equipped to protect the soil and groundwater. A roof allows falling rainwater to be drained off separately without becoming contaminated.

Traffic Zone. The traffic zone of an intermediate storage site is where hazardous wastes are transported to and from the storage and processing zones. The traffic zone must be impermeable to liquids and able to bear heavy loads. It must be large enough to allow vehicle operation without collisions and should offer free access to:

1) Rainwater and fire fighting water retention basins
2) Blind manholes and other inspection shafts
3) Onsite filling station for plant vehicles
4) Final pre-release inspection tank for wastewater
5) Car/truck wash
6) Substation and electrical distribution
7) Parking area

Storage Zones. Because hazardous wastes brought to the facility for intermediate storage come in a wide range of consistencies and are shipped in different kinds of containers, several storage zones have to be provided. Solids boxes or sludge pits are provided for solids, including pressed sludge filter cake, that arrive loose in containers or skips. The wastes are held and combined into larger units for shipping to the disposal site. As required by regulations, these storage areas are impermeable so as to protect soil and groundwater and are also roofed.

Another zone comprises roofed-over areas, isolated from the soil, where wastes delivered in skips and containers and destined to be held therein until further shipment can be set down and stored temporarily. Liquid and flammable hazardous wastes are commonly placed in separate tanks, located in a dike that retains leaks.

Hazardous wastes delivered in drums merit special attention. A drum storage area is provided where these drums and casks can be put in intermediate storage and combined into larger transport units. Generally, drum and cask storage zones are subdivided into sections for flammable and nonflammable substances as well as toxic and highly toxic substances. Casks and drums are held on pallets or in special trailers that can be used for forwarding.

In intermediate storage sites with treatment plants, a special zone must be kept free for wastes from transportation accidents, wastes generated by malfunctions, and wrongly declared wastes.

Treatment Zone. The treatment zone includes the organic and inorganic trains of the physicochemical treatment system with the appurtenant retaining basins and transfer equipment (see also Section 9.1). Separate systems are provided for organic wastes (wastes containing halogenated organic solvents, wastes containing nitrites, those containing cyanides, and miscellaneous organic wastes) and for inorganic wastes (alkaline wastes, wastes containing nitric acid and nitrates, those containing cyanides, nitrites, and chromates, and miscellaneous inorganic wastes).

The essential operations in the processing equipment are as follows:

1) Removal of coarse material
2) Separation of emulsions by chemical breaking, thermal treatment, and membrane techniques
3) Precipitation of metal salts
4) Sedimentation of sludges and slurries
5) Filtration of sludges in recessed-plate filter presses
6) Treatment of wastewaters (e.g., air stripping and activated- carbon filtration)

Figure 85. Schematic of the physicochemical treatment plant at Frankfurt/Main

7) Treatment of waste air, mainly in scrubbers and activated- carbon filters

Figure 85 shows of the physicochemical treatment system in the Frankfurt/Main intermediate storage site.

8.4. Procedures at an Intermediate Storage Site

An intermediate storage facility operates five days a week. Deliveries and transfers of wastes take place in the daytime; deliveries outside of normal receiving hours are possible only in emergencies. The physicochemical treatment plant runs on one or two shifts. Including plant management and laboratory personnel, around 25 employees perform all the work required in the intermediate storage site.

Wastes are delivered in tank trailers and trucks, skips, containers, and drums. Every delivery must be reported in advance by a waste disposal and recycling certificate. Before delivery is made, a schedule including quantity, type, and form of the hazardous waste is agreed on with the intermediate storage site. Manifests accompanying the delivery must identify producer of waste, transporter, and all substance-specific data for the wastes. Vehicles delivering hazardous waste are weighed on entry into the facility and their papers are examined to make sure they are properly completed. Next, a sample is taken from each load at the sampling station for incoming analysis in the laboratory. An internal load ticket is prepared with data from the first (declaration) analysis, which are compared with laboratory measurements and verified.

In the laboratory, the storage location, nature of processing and disposal, and disposal costs are set for all hazardous wastes received. Information about the unloading of wastes and the name of the responsible employee are entered on the internal ticket. This is the person who signs the receipt for the wastes and supervises

unloading. In this way, proper sorting and classification of wastes is ensured.

Drums and casks are subject to special handling, since improper handling of wastes, especially in drums, can have serious consequences. For this reason, every drum must have an adhesive label listing essential data such as the address of the waste producer, the type of waste, the container contents (quantity, composition, and consistency), and hazard warnings.

Drum labels are generally numbered in sequence, both with numerals and in barcode. All relevant data, such as drum number, internal load ticket, and so forth are collected with a data reader. These data are stored in the computer and the drum is placed in the drum storage area. In this way, a given container can be precisely located at any time. If the cask is later to be shipped away, for example in a trailer going to an incinerator, the data are forwarded electronically and the container is deleted at the intermediate site.

The recording, identification, and classification of all incoming hazardous wastes makes it possible to devise an overall logistical scheme. The dispatching office can then dispose the wastes according to how they can be processed or incinerated with allowance for the storage capacity. The chemical composition of the wastes is particularly important in this respect. The logistical system is important and helpful in, for example, incineration scheduling, where incineration and flue-gas cleaning must be adapted to the inlet pollutant levels. Furthermore, inclusion of all wastes in the logistical system makes it possible to report on the quantity, nature, composition, and current location of wastes at all times as required by the Industrial Emergencies Regulation (Störfallverordnung). Individual sites can thus be operated in accordance with waste composition and hazard potential, so that appropriate fire fighting measures can be employed in case of a fire.

8.5. Soil Protection

Stands and storage areas must be made suitably impermeable to prevent chlorinated and other halogenated hydrocarbons entering the soil and groundwater.

Chlorinated hydrocarbons have high vapor pressures and are relatively volatile, with relative vapor densities > 1, so that their vapors readily sink to the ground. The liquids are heavier than water, and are not readily ignitible. They are decomposed by the action of light and heat, yielding hydrochloric acid. The design and construction of soil protection measures must take all these properties of chlorinated hydrocarbons into account.

The type of soil protection depends on the degree and nature of use of the area in question. For example, storage zones with heavy traffic loads (e.g., skip and drum storage areas) must be made so that the traffic surface can withstand mechanical wear. As a rule, the protective arrangement here consists of two concrete courses with an intermediate layer of sheet steel or high-density polyethylene. The tightness of the surfaces must be verifiable, for example by vacuum testing, extraction and analysis of soil air, or leak monitoring.

Indoor areas meant to hold pollutant-laden liquids, such as drainage basins, tank complexes, self- contained drainage systems, and interceptor pipes, can be lined with poly(vinylidene fluoride) slabs, stoneware tiles impermeable to volatile halogenated hydrocarbons, or sheet steel. Again, the tightness of these surfaces must be verifiable.

Figures 86, 87, 88, 89, 90 show proven designs for soil protection.

8.6. Conclusions

Intermediate storage facilities have proved to be the best approach to wide-area collection of hazardous wastes. These sites, including those specialized for small quantities of hazardous wastes, are an important component of waste management. Proper sorting and pretreatment of hazardous wastes in intermediate sites can reduce transport quantities and distances and minimize danger to the public. Intermediate storage facilities must comply with all applicable laws, regulations, and codes and must keep up with the state of the art.

9. Treatment of Waste

9.1. Physicochemical Treatment

9.1.1. Introduction

The waste disposal chain ends at the landfill. Against the background of long-term landfill problems, it has become accepted that today's landfills must not become the contaminated sites of tomorrow. One consequence is that requirements on residues to be disposed of are becoming more stringent. Thus wastes intended for final disposal in landfills must not generate emissions that pollute groundwater, soil, or air.

When low-waste technologies [276] cannot be used to abate wastes and the wastes themselves cannot meet the criterion of "emission neutrality," thermal or physicochemical processes, or biological ones in some cases, must be employed for waste pretreatment.

This section deals with methods for the physicochemical treatment of wastes. The background for the discussion is the Second General Administrative Regulation pursuant to the German Federal Waste Act (Abfallgesetz), entitled " Technical Directive for Hazardous Waste" (TA Abfall) [277]. Among others, this regulation contains a complete list of requirements for stateof-the-art physicochemical processing plants. As the only statutory regulation embodying a detailed technical code, the TA Abfall has an influence reaching beyond Germany, serving as an acknowledged model within the European Union.

9.1.2. Types, Origin, and Properties of Wastes

To ensure consistent performance in waste disposal in the Federal Republic of Germany, the federal states in a cooperative body called Länderarbeitsgemeinschaft für Abfall (LAGA) [278] have prepared a "waste catalog" in which each waste is listed along with the treatment and disposal method that best meets environmental standards. The waste types of interest here are those for which the waste catalog prescribes physicochemical treatment. These fall into two groups:

1) Wastes with predominantly inorganic pollutants
2) Wastes with predominantly organic pollutants

Most such wastes have a liquid to pumpable consistency.

The first category includes alkalies, acids, electroplating sludges that have not been dewatered, concentrates, semiconcentrates, and rinsing waters from the chemical industry, from surface treatment and finishing (pickling and electroplating), and from the automotive and allied industries.

Wastes in which the pollutants are primarily organic include emulsions, wastewaters containing oil, synthetic coolants and lubricants, polymer emulsions, and organically loaded rinse and wash waters from the metalworking and automotive industries, from vessel and tank cleaning, from transportation facilities, and from military and comparable installations.

In both groups, the main component is water. Nonetheless, these wastes are not wastewater but hazardous wastes, because releasing them into sewerage without pretreatment is not permitted.

Inorganically contaminated wastes contain water-soluble compounds that are used in the above-mentioned industries. The cations are often nonferrous metals of groups 8 – 12 of the periodic table, such as copper, zinc, cadmium, and nickel. Toxic anions include chromate, dichromate, cyanide, and nitrite. Other typical wastes of this group are spent acids and alkalies. Along with chlorides and sulfates of the alkali and alkaline-earth elements, the burden of neutral salts often includes the corresponding ammonium compounds.

Complexing and chelating agents play a special role.

The main pollutants in the second group of wastes, with contaminants mainly organic in character, are aliphatic hydrocarbons such as those found in petroleum products. These can occur as "free" oil or dispersions and emulsions. In the latter case, the waste also contains emulsifiers such as anionic polyelectrolytes. Many other water-soluble organic products are also present, including surfactants, glycols, polar and nonpolar solvents (e.g., halogenated hydrocarbons), and aromatics with polar groups.

The total amount of water-soluble organic species is indicated by the chemical oxygen demand (COD), which ranges from a few thousand to a few hundred thousand milligrams of oxygen per liter.

Both groups of waste generally contain suspended solids of various particle sizes.

9.1.3. Treatment Processes

Physicochemical treatment processes have their origin in industrial wastewater treatment. Because of the complex composition of the wastes and the increasingly stringent requirements on the quality of liquid and solid residues generated in their treatment, this technology has continued to develop independently.

Many of the unit operations known from chemical technology are employed in physicochemical waste treatment in supra-regional hazardous waste disposal centers worldwide.

The techniques include mechanical, physical, chemical, and biological processes:

1) Mechanical processes: sedimentation, decantation, filtration (special cases: micro-, nano-, and ultrafiltration)
2) Physical processes: flotation, adsorption, ion exchange, distillation, stripping, reverse osmosis, evaporation, crystallization
3) Chemical processes: (leaching), neutralization, oxidation, reduction, precipitation, extraction
4) Biological processes: aerobic and anaerobic biodegradation, biological nitrate elimination

Not all these processes are equal in importance and scope of application. The physicochemical processes such as stripping/evaporation/crystallization [279] or reverse osmosis, and the biological processes are being used increasingly in waste treatment in response to rising standards.

Further impetus for physicochemical treatment has come from the development of methods for the purification of particular liquid wastes of complex composition. These wastes include leachates from municipal and hazardous waste landfills, which have high loads of both organic and inorganic species. In general, only a combination of methods – such as biological treatment, reverse osmosis, and evaporation/drying – can give a satisfactory result in such cases [280].

Progress in wet oxidation processes with H_2O_2 or ozone, utilizing catalysts or UV light [281], has been spurred by the same needs.

Electrochemical methods (cathodic deposition of nonferrous metals, anodic oxidation of cyanides and water-soluble organics) are of increasing interest. In future, because of the possible reclamation of substances from wastes, electrochemical processes combined with, e.g., solvent extraction [282] and electrodialysis will become more important.

Another process, developed in the United States and the United Kingdom, is the oxidation of dissolved and suspended, difficultly degradable organic compounds in supercritical water [283].

9.1.4. Requirements for Construction and Operation of Physicochemical Treatment Plants

TA Abfall includes provisions on process engineering, residues and wastewater, and instrumentation and control in physicochemical treatment plants. The goal of physicochemical treatment, as defined in this regulation, is that the treated waste be rendered recyclable or disposable by a downstream operation such as incineration or landfilling.

Treatment Plan. Prior to industrial-scale treatment of a waste, a treatment plan must be prepared on the basis of laboratory tests. Wastes delivered to public physicochemical treatment facilities are commonly single batches of multiply and severely contaminated material that the generating plant cannot handle in its own wastewater treatment system because of expected complications (e.g., the presence of complexing agents).

The waste disposal operator must therefore conduct lab trials to identify the treatment steps for each batch. For example, the treatment chemicals and their quantities must be determined to sufficient accuracy and passed on as instructions to the operating personnel.

Organic and Inorganic Treatment Trains. The "treatment trains" for organically and inorganically contaminated wastes should be separate because they differ in their chemical and physical properties. This also avoids mixing of wastes and makes it possible to meet the differing requirements for the disposal of the resulting solid and liquid treatment residues. The following processes are considered state-of-the-art for the organic treatment train: distillation, chemical emulsion breaking, and membrane processes.

In addition to these basic processes, the overall process must also include other unit operations. For example, the proper treatment is often preceded by the separation of solid and liquid contaminants. This holds equally for the organic and inorganic trains.

A variety of total concepts are under discussion for the treatment of inorganic wastes, and a distinction is made between monofunctional and multifunctional utilization of plant sections.

In a monofunctional plant, only one quite definite treatment, such as cyanide oxidation, can be performed. A multifunctional plant design, in contrast, makes it possible to interconnect the plant components flexibly, so that a variety of reactions can be carried in the same portion of the plant.

Precipitation of heavy metals is a point of central importance in inorganic treatment, because of their high water-pollution potential.

Dissolved heavy metals are first precipitated as hydroxides or hydrated oxides. If hydroxide precipitation does not meet the required limit, a second stage, such as sulfide precipitation, is added. Sulfide precipitation alone is not permitted due to the toxicity of hydrogen sulfide and the possibility of remobilizing processes acting on heavy metal sulfides in the landfill.

Posttreatment. Classical treatment processes are often insufficient for ensuring compliance with present emission limits. For such cases TA Abfall specifies possible posttreatment steps. Supplementary treatment processes downstream of the organic train include stripping, activated- carbon adsorption, and biological treatment; downstream of the inorganic train, reverse osmosis and evaporation.

Instrumentation and Control. All processes involved in physicochemical treatment require monitoring. This is especially true of processes generating potentially toxic substances as intermediates or byproducts. The degree of automation of these operations has to be determined case by case; it depends on the composition of the inlet wastes, among other factors. As a rule, physicochemical treatment plants run by hazardous waste disposal companies are operated in batch mode. This is how they differ from industrial wastewater treatment systems, which normally are operated in continuous (flow-through) mode.

9.1.5. Technological Concept of Physicochemical Treatment Plants

A comparison of existing physicochemical treatment systems operated by the major hazardous-waste disposal companies shows that the process engineering is quite similar from one to another. For example, sludges from neutralization and hydroxide precipitation are always dewatered in recessed-plate filter presses.

9.1.5.1. Treatment Plant for Inorganically Contaminated Wastes

Figure 91 presents the flowsheet of a conventional physicochemical treatment plant for waste with predominantly inorganic pollutants.

The plant consists of the following units:

1) Separate receiving and holding basins for acid wastes, alkaline wastes containing cyanides and nitrites, wastes containing chromates, and neutral sludges that have not been dewatered
2) Chemical tanks for acids, alkalies, and other treatment chemicals such as sodium hypochlorite, sodium hydrogensulfite, hydrogen peroxide, and flocculation aids
3) Reaction vessels of multifunctional design in which any treatment operation can be performed in any vessel
4) Dewatering (thickener, sludge pump, and recessed-plate filter press)
5) Final wastewater tanks, which are filled, then inspected by the laboratory, and finally discharged

This physicochemical treatment system is a widely used classical solution. The technical provisions of the Technical Directive on Hazardous Waste (TA Sonderabfall), as well as wastewater standards now in force or being prepared, require a more complex plant configuration.

An advanced concept, essentially oriented to the TA Sonderabfall provisions, includes the following:

1) Twelve receiving stations, for example, stations for neutral sludges; acids; alkalies; sludges containing cyanides, chromates, nitrites, and complexing agents; acid wastes containing HNO_3; etc.
2) An appropriate number of vessels for intermediate waste storage
3) A chemical supply system

An advanced treatment section includes four independent pretreatment lines ("main detoxification"):

Figure 91. Conventional physicochemical treatment system for wastes containing inorganic contaminants
a) Incoming waste basins; b) Holding basins; c) Recessed-plate filter press; d) Off-gas cleaning unit; e) Chemicals station; f) Treatment vessels; g) Emergency valve

1) Metal hydroxide and neutral sludges as well as acid wastes
2) Sludges containing cyanides, chromates, and nitrites; alkaline sludges
3) Complexing agents
4) Emulsions containing cyanides, nitrites, and other inorganic contaminants

Discharges from the first two treatment lines pass via buffer storage to a common final treatment step, operating in continuous mode. After sulfate precipitation and alkalization, the operations performed here include AOX/NH_4 stripping, multiple-bed filtration (to remove fine solids), selective cation-exchange treatment (to remove heavy metals), UV/H_2O_2 treatment (to remove organic species), and filtration with activated carbon.

Wastes containing complexing agents have their own separate treatment system. Contaminated emulsions are subjected to preliminary detoxification and then fed to an independent physicochemical treatment unit.

9.1.5.2. Treatment Plant for Organically Contaminated Wastes

Figure 92 shows the flowsheet of a conventional treatment system for organically contaminated waste of liquid to pumpable consistency. The major difference between processes in existing plants is the method used for emulsion breaking. Techniques employed are chemical salt separation (precipitation/flocculation), thermal breaking (evaporation), and membrane processes (ultrafiltration).

The process generally includes the following steps:

1) Acceptance

Figure 92. Conventional physicochemical treatment plant for wastes containing organic contaminants
a) Settling basin (four chambers); b) Screens; c) Holding basins; d) Flocculant metering station; e) Pumping station; f) Decanter; g) Sludge pump; h) Oil separator; i) Chemicals station; j) Reaction vessels; k) Compressed air station; l) Sludge thickener; m) Paper belt filters; n) Flow measurement; o) Emergency valve

2) Separation of solids by sedimentation, supplemented by mechanical separation (e.g., decanter or centrifuge) if required
3) Separation of light oversize material and free oil
4) Holding for homogenization
5) Emulsion breaking
6) Reaction sludge separation (only when salt separation is used in conjunction with precipitation/flocculation) by flotation, filtration, or centrifugation
7) Wastewater holding for final inspection before discharge

The flowsheet of a modern plant, complying with TA Abfall, for treating organically contaminated hazardous wastes is shown in Figure 93. This system features improvements in acceptance and pretreatment of wastes, with modified emulsion breaking, efficient waste air treatment, and equipment for the removal of volatile and nonvolatile halogenated hydrocarbons.

The principal advance over conventional systems, however, is in the posttreatment of the wastewater. In the example shown, denitrification is followed by two-stage aerobic biological treatment. Each of the two activated sludge stages includes an activated sludge tank and a settling tank.

Results from the operation of one such plant [284] show a 60 – 90 % reduction in COD and > 90 % reduction in BOD_5.

9.1.6. Environmental Requirements

Residues. Processing of inorganically contaminated wastes generates metal-containing hydroxide sludges in the form of filter cakes, dewatered in filter presses. These filter cakes must be deposited in hazardous waste landfills unless facilities exist for processing them to reclaim their nonferrous metal content.

Physicochemical treatment plants for organically contaminated wastes must be integrated with hazardous-waste incineration plants for

Figure 93. Advanced physicochemical treatment system with final biological treatment for wastes with organic contaminants a) Preliminary detoxification basin; b) Rotary screen; c) Incoming waste basin; d) Holding basin; e) Sludge separation; f) Reaction vessel; g) Flotation; h) Supply vessel; i) Activated sludge tank; j) Secondary settling tank; k) Biological waste-air filter; l) Activated carbon filter

disposing of the oil-containing solid and liquid residues produced.

Wastewater. The treated wastewater discharged as the end product of physicochemical treatment is stored in final inspection tanks before being released. Complete laboratory tests must be performed to ensure that regulatory standards are met.

Physicochemical treatment plants of conventional design (Figs. 91 and 92) were generally able to satisfy legislative requirements on wastewater quality up to the mid-1980s. Standards have since become much more stringent as a result of new legislative and regulatory provisions, and this development is expected to continue in the short term. Examples of new statutory regulations can be found in the amended Water Resources Management Act (Wasserhaushaltsgesetz, WHG) of the Federal Republic of Germany adopted on September 23, 1986; to date, more than 50 general wastewater regulations have been issued pursuant to § 7a of WHG, establishing minimum standards for wastewater quality in various industries. A draft regulation entitled "Treatment of Production-Specific Residues and Product Residues" will set forth higher standards for the quality of waste-water from physicochemical treatment plants. For selected parameters, Table 18 gives limits dating from the 1970s, corresponding values from the late 1980s, and anticipated values taken from the draft regulation.

Waste Air. When organically and inorganically contaminated wastes undergo physicochemical treatment, waste air contaminated with pollutants is produced. In the first case, the off-gas contains volatile organic substances such as short- chain aliphatic and aromatic hydrocarbons, volatile halogenated hydrocarbons, and odorous nitrogen and sulfur compounds.

Waste air is generally treated with activated carbon, which in turn has to be disposed of as waste after use. When activated carbon is used, displacement reactions between species that compete for adsorption sites must be considered. To prevent breakthrough of pollutants, the activated carbon must be replaced before it is exhausted.

Table 18. Development of emission limits for selected substances from physicochemical treatment plants

Parameter	Unit	1979 limits	1989 limits	Draft limits 1992
Cadmium	mg/L	3.0	0.1	0.2
Chromium (VI)	mg/L	0.5	0.1	0.1
Copper	mg/L	1.0	0.5	0.5
Nickel	mg/L	2.0	0.5	1.0
Ammonium	mg/L		200	10.0 (NH_4-N)
Nitrite	mg/L	30	5.0	2 (NO_2-N)
Nitrate	mg/L			20 (NO_3-N)
COD	mg O_2/L		900	200
Hydrocarbons	mg/L	5.0	10.0	2.0
AOX	mg/L		1.0	1.0

Odorous substances present in low concentrations, if they are biodegradable, can also be removed on biofilters. An air treatment system for an organic physicochemical treatment plant is reported in [285]. It splits the air stream into a smaller stream with a high burden of hydrocarbons and volatile halogenated hydrocarbons, which is led through an activated carbon filter, and a stream about ten times larger in volume, which mainly contains odorous substances. This larger stream can be effectively cleaned by passing it through a biofilter (area 200 m^2, bed depth 1 m).

Exhaust air from inorganic physicochemical treatment systems contains volatile reaction products and intermediates, such as nitrogen oxides, acid-containing aerosols, and ammonia, but also volatile organic compounds. These substances are removed in a packed-tower wet scrubber, sometimes combined with activated carbon filters.

9.1.7. Storage and Transportation

Storage. Among the provisions dealing with the storage of liquid wastes is the "Regulation on Facilities for the Storage, Filling, and Transfer of Water-Polluting Substances" (Verordnung über Anlagen zum Lagern, Abfüllen und Umschlagen wassergefährdender Stoffe, VAwS) [286].

A fundamental requirement is chemically appropriate layout of tanks. For example, the positioning of a storage tank for cyanide-containing wastes next to a vessel for acid wastes is not acceptable.

Tanks must be placed in catch trays, which must be made of materials resistant to the tank contents. When the presence of halogenated hydrocarbons cannot be ruled out, the authorities require monitorable floor protection resistant to volatile halogenated hydrocarbons (e.g., a steel liner).

The tanks must be made of resistant materials. Steel vessels with corrosion-resistant coatings and tanks made of polyethylene or polypropylene have proved suitable.

Water quality law in the Federal Republic of Germany generally requires design approval for storage tanks; for special designs, approval by an authorized agency such as the Technischer Überwachungsverein (TÜV) is necessary.

Because liquid wastes generally contain suspended solids, tanks must have conical bottoms and stirrers to ensure homogenization.

Because of the hazard potential of wastes held in temporary storage, regulations such as TA Abfall set strict requirements on tank instrumentation and monitoring. Level measurement is required in every case, together with safeguards against overfilling. Temperature and pressure monitors may be required on a case-by-case basis.

Because the tanks must be cleaned regularly to remove encrustations and deposits, they must be provided with access and inspection holes.

Transportation of liquid wastes from the waste-producing site to the disposal site is subject to strict regulations.

Suitable vehicles, such as chemical-resistant suction vehicles, are required for shipping large quantities (5 – 12 m^3). Small quantities may be transported only in safe containers, such as approved-design cubic tank containers or drums.

As a rule, only duly licensed trucking firms may transport such wastes. To obtain regulatory approval as a carrier, a company must demonstrate the technical suitability of its fleet and the technical knowledge and skill of its personnel.

The hazardous properties of wastes require that proper occupational health and safety practices must be in effect wherever employees may be exposed to wastes while handling them (draining, filling, sampling). This ranges from protective clothing, gloves, spectacles or goggles, and protective masks to coveralls and full respiratory protection. Personnel working in treatment plants are subject to continuous medical surveillance.

9.1.8. Legal and Economic Aspects

The legal framework is that of environmental law. Along with waste management law and the related regulations (e.g., TA Abfall and the Waste Transportation Regulation (Abfallbeförderungsverordnung) mentioned above), applicable fields of law include pollution control (environmental compartment: air), water quality (environmental compartment : water), and numerous administrative and other regulations and technical guidelines.

In addition to national law and, in part, superior to it, there are also a number of EC directives either in force or being prepared to create unified standards for the treatment of hazardous wastes in the European Union.

The large number of legislative provisions and stringent technical requirements for environmental protection have their price. Physicochemical treatment of hazardous wastes is a cost-intensive operation. Disposal costs include the high capital costs of the plant and depend on the type and concentration of the pollutants being treated.

Another factor contributing to the high costs is the disposal of the solid residues generated in physicochemical treatment. These residues require hazardous waste landfills or hazardous waste incineration plants. In 1993, the cost of physicochemical treatment was 150 – 1500 €/t, with an average of ca. 260 €/t.

9.2. Hydrolysis and Alcoholysis of Plastics Wastes

9.2.1. Introduction

Because of the growing amount of waste being produced and increasing environmental consciousness, recovery of raw materials from wastes is becoming of increasing importance. In 1989, with an output of ca. 9×10^6 t of plastics, the Federal Republic of Germany generated ca. 2.2×10^6 t of plastics wastes [287]. Of this, ca. 500 000 t of sorted and 15 000 t of mixed residential waste was recycled. In 1992 ca. 45×10^6 t of plastics were used in Germany. These quantities show how important recycling of plastics wastes is going to be in the future. The thermal and chemical processes now used for plastics recycling can be classified in two categories [288]: 1) energetic utilization (combustion) and 2) material reclamation by chemical reaction (pyrolysis, hydrolysis, hydrogenation). The processes that have so far found large-scale application have been those involving energy utilization. A pilot plant operated at Bottrop by VEBA Öl is hydrogenating plastics wastes to obtain a naphtha-like mixture of hydrocarbons. Other pilot and demonstration facilities are in the planning stage.

Hydrolysis and alcoholysis processes for recovery of feedstocks from plastics wastes have not yet been studied in depth. This section therefore gives a summary of scientific and application-oriented research reported in the specialist and patent literature, as of well as planned processes.

9.2.2. State of the Art

For a plastic to be broken down into its monomeric constituents by hydrolysis or alcoholysis, its polymer structure must contain polar groups (ester, amide, urethane, carbonate, or acetal) along with the hydrocarbon groups. Such a polymer can be decomposed under relatively mild conditions with the use of various additives. Aminolysis is of secondary importance and is not discussed here.

9.2.2.1. Hydrolysis of Polyurethanes

Polyurethanes are bulky plastics (density ca. 30 kg/m^3, storage volume ca. 35 m^3/t). The environmental and economic problems linked with their high bulk volume, plus the relatively high manufacturing cost (13 – 15 €/kg), make an economical reprocessing method necessary. Polyurethanes are unstable when heated, but thermal processing yields numerous degradation products, which are so diverse that they cannot be reclaimed. However, the use of selected chemical recycling methods offers some advantages. The hydrolysis of polyurethanes is carried out at high temperatures and pressures to increase the reaction rate [288–291]. Reaction products include CO_2 and the polyether alcohols, polyester alcohols, and amines used as feedstocks in the original plastics production process (Scheme 1).

Hydrolysis Plant. Processes reported in the literature are of batch [289], [290] and continuous extruder types [291]. Figure 94 shows a flowsheet for a continuous pilot plant hydrolyzing flexible polyurethane foams [287], [291]. The foam, produced from toluene diisocyanate and polyols, is decomposed, whereby the isocyanate portion is broken down into the original toluenediamine (TDA), of which 90 % is recovered.

The decomposition of polyurethane in the presence of water is completed within ca. 2 h at 473 K; if the reaction temperature is increased by 10 – 15 K, the residence time required for complete reaction is halved. However, if the temperature is too high, the monomers obtained are not well-defined and, hence, not reusable.

The continuous process of Figure 94 is made possible by a twin-screw extruder that generates and maintains a constant steam pressure of 15 – 30 bar at reaction temperatures of 473 – 503 K. The PUR foam wastes, reduced to flakes or powder, enter a hydrolysis screw continuously via a metering screw. The hydrolysis screw operates at up to 573 K and 100 bar. Physical degassing of the plastic takes place in the compression zone. The pitch of the screw flight in the barrel decreases stepwise, giving a high degree of compression. In this way, the barrel is divided into three compression sections plus the reaction zone, which is separated from the upstream portion by a left-hand screw. Water required for polyurethane hydrolysis is injected by metering pumps and is vaporized in the extruder. Intensive mixing of water and plastic is promoted by kneader elements. The mean residence time of the mixture in the reaction space is ca. 20 min. The resulting mixture of gas (vapor) and liquid is continuously delivered to the reprocessing apparatus via a pressure release device. Volatiles entrained by product CO_2 and other gases can be recovered by condensation in a downstream cooler. Up to 90 % of toluenediamine is isolated from the product mixture in a complicated process involving aqueous acids. Integrated distillation and extraction stages are then used to separate all components. This is complicated by the emulsifiers from the polyurethane foam.

Separation of Hydrolysis Products – Physical Properties of Recycle Stream. The polyols can be recovered in pure form by reacting the crude hydrolysis product with oxalic acid. Oxalic acid and the resulting oxalate salt of TDA are only sparingly soluble in the pure polyol. The salt is removed by filtration, and adhering polyether is washed off with toluene. The toluene is distilled off to give an amine-free polyol. Alternatively, HCl gas can be admitted directly into the hydrolysis product. Under suitable reaction conditions (343 – 364 K, 50 % dilution of hydrolysis product with toluene), formation of TDA monohydrochloride is favored; this product can be recovered by filtration [291], [292].

The choice of separation process is dictated by the plastics waste being processed [291], [292]. The key parameters are chain length, degree of branching of the polyol, and hydrophilic character, which depends on the number of primary OH groups in the polyol. The process becomes more difficult if the PUR has been modified. For example, if it contains amine, the hydrolysis product derived from the standard flexible slab stock recipe is strongly alkaline. Hydrolysis of flame retardants containing phosphorus and chlorine yields phosphoric and hydrochloric acids, which form salts with the amines. If the mole fraction of acid-forming substances is greater than the amine content, the hydrolysis solution becomes acidic, and all the amines are present as salts; this complicates amine recovery. Amine yields are 85 – 92 %, depending on

the waste inlet to the process; polyol yields, in contrast, are largely independent of recipe and range between 95 and 98 %.

The quality of the recovered polyol is summarized in Tables 19, 20, 21 [291], [292]; oxalic acid was used to separate TDA. Table 19 compares the properties of a Bayer grade of pure polyether polyol with those of recycled polyol. The various compositions of standard flexible foams, obtained by manual foaming of mixtures of standard and recycled polyether polyols with toluene diisocyanate, can be found in Table 20. Table 21 describes the properties of the foamed products as well as their foaming behavior.

The data of Tables 19, 20, 21 show that technically acceptable products are obtained when recycled polyol is used. However, these results were obtained in manual foaming tests, and semi-industrial scale production processes must be used for a final assessment. Higher-quality recycled polyols can be obtained by HCl separation of TDA. Table 22 lists the properties of polyols as a function of the separation process and compares them with the standard product [292]. The low tinting values and improved color stability of polyols after HCl separation are especially promising for industrial reuse.

In addition to the tests on flexible slab stocks, flexible molded foams were broken down into

their chemical constituents so that the effect of formulation on both hydrolysis conditions and regenerate quality could be studied. The reaction conditions found for hydrolysis and TDA separation (HCl method) on flexible slab stocks were also applicable to this class of foamed plastics. Table 23 compares properties of the regenerated polyether polyols with those of a standard product (Desmophen 3900).

Like the commercial polyol Desmophen 3900, the regenerated polyether polyol exhibits good foaming properties. The molded foam showed tolerable deviations from commercial foams.

In conclusion, it must be stated that the hydrolytic reprocessing of plastics wastes has at present no prospects for development into a marketable process for economic reasons. Much more interesting are the alcoholysis processes, in which a variety of alcohols are used to decompose the plastics wastes into their basic components.

9.2.2.2. Alcoholysis of Polyurethanes

Unlike hydrolysis, the alcoholysis of polyurethanes does not generate CO_2 because the reaction products are more stable (Scheme 2) [287].

This reaction yields a mixture of the starting polyols and low molecular mass urethanes with ether terminal groups. If a diol is used for polyurethane alcoholysis, the reaction products have terminal OH groups and can thus be directly reacted with isocyanates. The use of special alcohols or diols in this degradation reaction makes it possible, during the actual recycling process, to match the properties of the product mixture to the intended application.

Extensive work on this recycling process has been reported in the literature [287]. Topics of study have included, in particular, the effect of different alcohols and catalysts on the product distribution. Higher-boiling glycols based on ethylene oxide and propylene oxide have proved suitable. With these cheap substances, used alone or mixed, the reactivity and the properties of the regenerated polyols can be controlled within certain ranges. Basic substances (amines, hydroxides, alkoxides) and Lewis acids catalyze this reaction.

Ford Motor Company has reported a combination of glycolysis and hydrolysis, called hydroglycolysis [293], [294]. If pure diethylene glycol is used to treat PUR wastes, a mixture of widely varying reaction products is obtained. The complex product distribution makes reprocessing difficult. The product spectrum is greatly simplified if small amounts of water (ca. 0.1 – 2.4 wt %) and basic catalysts are added to the reaction mixture. The only primary products in this case are toluenediamine and polyether triol. LiOH has been found to be a good catalyst for the reaction; NaOH, KOH, $Ca(OH)_2$, $Ba(OH)_2$, $Mg(OH)_2$, and $Al(OH)_3$ proved, however, unsuitable.

The polyol obtained by alcoholysis can be recovered in high purity by liquid – liquid extraction with high-boiling hydrocarbons such as hexadecane. The regenerated polyol can be reused in polyurethane synthesis after mixing with new polyol (1 : 1 ratio). A plant designed by Ford would be profitable according to cost estimates based on 1982 U.S. prices, if there is no opportunity to sell the PUR waste and the regenerated polyether, polyol can be returned directly to the production process.

In 1993, REGRA Recycling used alcoholysis of polyurethanes as the basis for developing a process suitable for total recycling of all PUR wastes generated in the production and processing of these plastics [295]. The regenerated polyol can be returned directly to the production process. The PUR wastes are ground and fed to an unpressurized reactor where the temperature is raised and alcohols and other unspecified additives are added. The polyurethane wastes are broken down into fragments of various size by chemical and physical processes. The product distribution (type of polyol) can be controlled by means of the reaction conditions (temperature, alcohol, catalyst). The filtered regenerated polyol can be held in supply tanks until it is reused.

Table 24 compares the physical properties of integral polyurethane foams, one made from pure polyol and the other with the addition of regenerated polyol. As in the hydrolysis case, there is no significant difference between the products.

9.2.2.3. Hydrolysis and Alcoholysis of Polyesters and Polyamides

Polyesters and polyamides can be broken down to low molecular mass starting materials by hydrolysis and alcoholysis processes analogous to those used for polyurethanes [288]. The hydrolysis of polyesters yields carboxylic acids and alcohols; these can be fed to the production process only after extensive treatment operations. The hydrolysis of polyamides generates the respective amino carboxylic acids or dicarboxylic acids and diamines.

The alcoholysis of polyesters leads to the corresponding diols and dicarboxylates (Scheme 3).

If poly(ethylene terephthalate), PETP, is alcoholyzed with methanol, the monomers required for the polymerization of this plastic can be regenerated. The use of polyfunctional alcohols leads to polyols, which can be modified as required for a variety of purposes.

Processes patented by DuPont illustrate several routes for regenerating the starting materials used in PETP manufacture. For example, terephthalic acid can be recovered in ca. 96 % yield by reacting PETP waste with NaOH in ethylene glycol at 363 – 423 K [296]. With regard to physical and chemical properties, PETP made from 20 % recyclate and fresh terephthalic acid showed no significant deviations from commercial products.

DuPont has also devised a process in which PETP wastes are reacted at 398 – 408 K in a solution composed of bis(2-hydroxyethyl) terephthalate (BHT, ca. three parts by weight per part of waste), ethylene glycol (20 – 30 wt %), sodium acetate (200 – 250 ppm), and water (1 – 3 %) [297]. The plastics wastes, consisting of at least 85 % ethylene terephthalate, are broken down into the monomers and esterified to BHT. The competing dimerization of the product ethylene glycol to diethylene glycol can be suppressed by adding BHT to the reaction mixture.

Michigan Technological University has developed a process in which terephthalic acid and ethylene glycol can be regenerated from PETP by NH_4OH catalyzed hydrolysis [298]. The ground plastics waste is reacted with a steam/ammonium hydroxide mixture at 477 K under a pressure of ca. 3100 kPa. The resulting ammonium terephthalate is treated with sulfuric acid at 296 K to give terephthalic acid and ammonium sulfate. The TPA can be separated and purified; the liquor goes to an ammonia stripper. The ammonia released is dissolved in water, and the solution is reused for depolymerization of PETP. Ethylene glycol accumulates in the bottom of the NH_3 stripper and is purified by distillation.

Toray Industries has described a process by which PETP wastes are depolymerized in a melt of BHT and ethylene glycol [299]. The reaction, carried out at 488 – 523 K, leads to bis(2-hydroxyethyl) terephthalate and its oligomers. The BHT feed is said to have a glycol/acid ratio of 1.3 – 2.0. Similar values are reported for the initial PETP/ethylene glycol molar ratio. The weight ratio of the acid component of BHT to recycled plastic should lie in the range 1 : 4 – 2 : 1 at the beginning of the reaction. This process allows the reaction time (τ = 30 – 90 min, depending on the feed ratios) to be shortened and the undesired reaction of glycol to diethylene glycol and other impurities to be suppressed.

In the United States, Coca-Cola is using methanolysis to decompose PETP bottles into their basic components in a process developed by Hoechst Celanese [300]. The regenerated terephthalic acid is so pure that it is approved for reuse in the production of PETP bottles. Currently, this is the only recycling process worldwide that yields a plastics product permitted for direct- contact food and beverage use. In comparison with the processes of Goodyear Tire and Rubber (glycolysis) and Eastman Chemical Products (methanolysis), it also has the advantage that colorless stock can be regenerated from used colored plastics.

A purely hydrolytic process for a wide variety of polymer wastes [PETP, poly(butylene terephthalate), nylon 6, and nylon 66] has been devised by Celanese Mexicana [301]. The plastics wastes are fed with water (12 parts to 1 part wastes) and reacted at 521 K under a pressure of 48 bar. After a residence time of 2 h in the reactor, the wastes are decomposed to their monomers. Addition of a decolorizing agent, mainly consisting of activated carbon, enhances the colorfastness of the reaction products. The hydrolysis solutions are worked up by crystallization and distillation.

Scheme 4. Basic hydrolysis of polyamide 66 with NaOH

A process for recycling polyamides is the phosphoric acid catalyzed hydrolytic treatment of nylon 6, yielding ε-caprolactam in monomeric and oligomeric form [302], [303]. The phosphoric acid catalyst must be used in large quantities because of deactivation pro-

cesses, and thus leads to corrosion of plant equipment.

Research at BASF has shown that polyamide 66 can be recycled by basic hydrolysis [302] to give hexamethylenediamine and sodium adipate (Scheme 4). Hexamethylenediamine is directly recycled to polyamide synthesis. Adipic acid is regenerated from its sodium salt by electrolysis. The other product, caustic soda, is recycled to the cleavage reaction. These studies have progressed only to the laboratory scale and are currently being scaled up [303].

9.2.2.4. Alcoholysis of Mixed Plastics

In the preceding sections various recycling methods for sorted plastics wastes have been described. More important is the processing of mixed plastics wastes into reusable products. Such processes are of particular interest in the automotive industry because large amounts of plastics blends are generated in manufacturing and in recycling of used cars. For example, cushion and upholstery wastes consisting of a mixture of polyester, polyamide, and polyurethane arise when auto seats are manufactured. The recycling process at Ford's plant in Cologne, for example, receives 1.5 t/d of wastes. Ford, Cologne, together with the German Federal Minister of Research and Technology and the German automobile and plastics industry association, commissioned the development of a process [304] by which polymer wastes from auto seat manufacturing, partly mixed with textiles, could be processed into polyols on a demonstration scale. The polyols can be reused for cavity-filling foams in the automobile or as a feed for semirigid structural insulating foams.

This research project has led to a continuous plant with two stirred-tank reactors and a plastics capacity of ca. 100 kg/h. Figure 95 shows a flowsheet of the plant.

The weight ratio of solvent (diethylene glycol) to plastics waste was 2 : 1; in continuous operation, a maximum plastics throughput of 60 kg/h was achieved with a reaction temperature of 483 – 493 K.

The plastics are completely dissolved and partially decomposed in the first reactor. The reaction goes to completion in the second reactor. Acrylic acid was used to catalyze the alcoholysis reaction in some trials.

Both the catalytic and the noncatalytic reaction yielded a polyol that was suitable for polyurethane synthesis despite its broad molecular mass distribution.

Economic estimates based on the demonstration plant indicate that a competitively priced polyol can be produced with full utilization of a plant handling 10 – 15 t/d of plastics.

9.2.3. Conclusions and Outlook

No plant or process is currently known that offers an expedient and economical process for the hydrolysis of plastics wastes. Chemical recycling of the original monomer building blocks will not be an alternative to existing processes for some years. The obstacles are extreme reaction conditions (supercritical water) and the associated plant costs.

In contrast, two alcoholysis processes are used industrially: methanolysis of PETP and regeneration of ε- caprolactam from nylon 6 (see Section 9.2.2.). More recent research and development has shown that not only pure plastics can be recycled by alcoholysis, but also that plants can be built for the alcoholysis of plastics mixtures under mild conditions of pressure and temperature.

In the automotive industry in particular, demand for recycling processes to regenerate chemically usable feedstocks from mixed wastes is going to grow. In view of environmental problems and political pressures, it will be of interest to create plants that can handle both wastes from auto seat manufacturing (polyurethanes, polyesters, polyamides) and plastics parts from recycled cars. However, much work is needed on these processes before the marketability of the recycled products can be guaranteed.

9.3. Incineration

Incineration is the most highly developed method of treating wastes. Wastes containing organic substances can be dependably processed in such a way that the residues can be disposed of without special precautions.

Modern waste gas cleaning processes make it possible to achieve emission levels that were

Figure 95. Block diagram of a pilot-scale plant for alcoholysis of automobile seat wastes

unimaginable just a few years ago. In industrial regions, the additional pollution due to modern waste incinerators is generally not detectable.

The following processes are employed:

1) For household and related wastes, grate firing
2) For sewage sludge, fluidized-bed firing; or this waste can be combined with household waste for grate firing
3) For industrial wastes classified as hazardous wastes, rotary kiln-firing

Industrial and commercial wastes such as packaging material, sweepings, and office and cafeteria wastes are classified together with residential wastes as "municipal-type solid wastes" or MSW and are incinerated together with household wastes in grate-fired incinerators. Small quantities of granular materials such as bleaching earths and catalysts can also be mixed with household wastes if the incineration plant is approved for this service. About 25 – 30 % of industrial and commercial wastes can be incinerated if thoroughly mixed with household waste; the heating value can be increased and made more uniform in this way.

Fluidized-bed technology is used in the large-scale treatment of sewage sludge. In Japan and Sweden, fluidized-bed furnaces are also used for MSW. Wood wastes, pretreated household waste, and contaminated soils have been incinerated in fluidized-bed pilot systems.

Solid and liquid residues from industrial production, in particular from the chemical industry, must generally be incinerated in rotary kilns if they contain organic matter and cannot be reclaimed by physicochemical treatment. This group of wastes includes oils, greases, tars, and pastelike to liquid residues from organic and pharmaceutical chemistry and from the petrochemical industry.

As a rule, centralized facilities are used; large chemical plants have incinerators close to the point where the wastes originate. In the latter case, the incinerator can be optimized for the specific properties of the residue.

Some wastes can serve as auxiliary fuels in industrial plants such as cement works and power stations.

The heat generated by incineration is utilized to generate power and provide remote heating.

Waste incineration has the following advantages:

1) Furnaces have been developed, built, and operated over a period of more than a century. Apparatus and methods are advanced and highly flexible.
2) Organic pollutants in the waste are destroyed with certainty by incineration.
3) Inorganic pollutants are concentrated in the residual fractions.

In high-temperature incineration processes, slag is withdrawn in liquid form, then pelletized wet. Most of the heavy metals are immobilized in this way, so that recycling or disposal of the slag presents no danger.

The melting of residues from grate-fired and fluidized-bed incinerators, which generate a mixture of ash, sinter, and slag instead of a fusible slag, is under investigation. In some cases, residues from flue-gas cleaning are added.

The process gives up to 95 % reductions in volume, so that far less landfill space is used up than if untreated wastes were disposed of.

Because waste gas cleaning methods are so advanced, emissions are below the mandated limits (in Germany those of the 17th Federal Pollution Control Regulation), often by as much as an order of magnitude.

The high level of development in waste gas cleaning means that waste incineration plants function as separation systems. The majority of the residues can be dumped in landfills. The

various residues from waste treatment are collected separately and deposited in hazardous-waste landfills if the valuable materials they contain cannot be reclaimed. In future, recovery of these materials will be required. Examples are the production of hydrochloric acid, sodium chloride, and gypsum. The metallurgical recovery of heavy metals from fly ash appears feasible in principle and is now being studied.

9.3.1. Grate Firing

Grate firing is the most widely used process for thermal treatment of wastes. Germany now has 51 plants in service; worldwide there are some 500. Figure 96 is a flowsheet of the Hamburg-Borsigstrasse plant, which came on stream in 1994 and represents the state of the art. The main steps in the process are as follows:

1) Waste receiving and preparation: scale, bin, crane, rotary cutter
2) Combustion and heat recovery: feeder, grate, air supply, combustion chamber, boiler
3) Waste gas cleaning: evaporative cooler, fabric filter, acid scrubbing, basic scrubbing, aerosol separation, SNCR denitrification
4) Wastewater treatment: HCl and gypsum recovery, wastewater evaporation

Figure 97. Grate-fired incinerator [308]

Combustion and Heat Recovery. The most important component of a grate-fired incinerator is the grate, which conveys the waste in a horizontal or inclined direction after the waste has been removed from the bin by a crane and has passed through the feed hopper and feeder. The grate is carried on a supporting structure built into the combustion chamber side walls in the underblast region; the grate proper consists of individual grate bars or grate rolls (Fig. 97).

Grate incinerators are classified according to how the charge is conveyed and rabbled. Types include reciprocating-bar stokers, single-stage and multistage, forward and reverse feed; pivoting step grates; single-stage and multistage traveling grates; roller grates; and reciprocating recirculating grates.

The grate itself can be horizontal, inclined down toward the end, or inclined up toward the end in the combustion chamber. It is bounded in front by the refuse feeding device (charging system), in back by the discharge device, and at the sides by walls, which can be uncooled, water-cooled, or air- cooled. The ash catchers are located below the grate; these also bound the underblast zones. Primary combustion air is delivered to the ash catchers through control valves; it is distributed beneath the grate as appropriate to the combustion process and forced by pressure into the combustion chamber through openings in the grate (free grate area).

Primary air passes through the grate in cross or oblique flow. The waste undergoes several partly overlapping processes: drying, degassing, gasification, combustion, and finally sintering to slag. These parallel reaction processes interact indirectly via the combustion chamber space above the grate, so that they can be well, and to a great extent individually, controlled even though there are no sharp boundaries between them.

Grate firing has the disadvantage that the generation of reaction products is largely uncontrollable. In the boundary zone between the drying and combustion steps, degasification processes generate carbon compounds that cannot be completely destroyed in the combustion space. A similar situation occurs in the boundary zone between combustion and cooling, where the production of sinter is a more or less random process that depends on process control and the quality of the feed material.

In modern incinerators, primary air is admitted substoichiometrically. The unburned gases generated as a result, chiefly CO and H_2, are combusted by admitting secondary air to the combustion chamber. This two-stage combustion system gained acceptance in the 1960s. The reason was that the heating value of waste increased so that the temperature in the charge bed often exceeded the melting point of the slag, which formed deposits on the grate and the furnace side walls, interfering with operation.

Grate-fired incinerators must meet the following requirements:

1) The primary air flow rate must be variable over sufficiently wide ranges with respect to the length and width of the bed of material on the grate
2) The primary air supply must not be impaired even after prolonged mechanical and thermal stress resulting from normal operation
3) The outlet holes for primary air in the grate structure must not become plugged or enlarged during operation
4) The rate of bed movement on the grate must be separately variable for each grate zone
5) The depth of the waste bed on the grate and the position of the combustion zone must be controllable
6) The waste should be thoroughly stoked and turned
7) The combustion process must generate as little fine dust as possible
8) There must be provision for keeping the waste/slag layering uniform over the entire area of each grate zone
9) Primary air channeling must be avoided
10) The quantity of material falling through the grate must be small and there should be a reliable means for removing this material
11) The primary air should adequately cool the grate under all operating conditions
12) The system must also have the capability of running on preheated combustion air and with recirculating off-gases admitted at selected points
13) Control should be largely automated and the system must respond immediately to control actions
14) Rapid startup and shutdown of the incinerator must be possible
15) Sintering and deposition of material on the grate, as well as scaling and corrosion of the grate, must be prevented
16) The grate bars must be easily and quickly replaceable
17) Reactor runs should be as long as possible

Combustion Chamber. Combustion takes place in the combustion chamber, which is bounded below by the grate, to the sides by cooled or uncooled walls, and above by a roof or boiler heating surfaces. The heat evolved here must be removed.

Only a small amount of waste is burned on and immediately above the grate, since the content of volatiles is high. The main process in the incinerator is combustion of volatiles in the combustion space above the solid waste. External, visible signs of this type of combustion are long flames in the combustion space, often up to a meter high. In contrast, the flame length when bituminous coal is burned is just a few decimeters, depending on the quality of the fuel (i.e., the content of volatiles).

The gas flow pattern is characterized as cocurrent, countercurrent, or mixed (central feed), depending on the geometry of the combustion space, which is defined by the following parameters:

1) Shape and size of the grate. The combustion space is bounded below by the grate, whose length and inclination largely determine its geometry.
2) Process zones on the grate. To allow for different-sized drying, degassing, combustion, and burnout zones, the combustion space must permit fast introduction or removal of heat.
3) Turbulence and homogenization of flue gas flow. Thorough mixing of the off-gases is essential for their complete combustion.
4) Residence time of combustion gases in the hot combustion zone. An adequate reaction time at high temperatures must be provided to ensure complete combustion of gases and solids.
5) Partial cooling of off-gases. To prevent sintering of fly ash to the walls and in the boiler, the off-gas temperature at the end of the combustion space must be limited.

The design of the combustion chamber is a compromise because the requirements change with the properties of the fuel. The gas flow pattern (cocurrent, countercurrent, mixed) is chosen to suit the actual requirements.

Because of the risk of deposits and corrosion, there are no internals in the combustion space or the first boiler flue pass. Heat transfer to the boiler in these zones is radiative.

Because the off-gases are deflected several times before entering the convection section, the gases are thoroughly mixed and the temperature is distributed over the cross section. Because the volume of the combustion space plus first, second, and third flue passes is very large, the residence time of the combustion gases in the radiant section is prolonged while the thermal loads per unit volume, unit cross section, and unit heating surface are reduced. The large gas-side flow cross sections permit low gas velocities, resulting in a low dust load in the gases downstream of the combustion space.

In continuous operation with contaminated heating surfaces, the off-gas temperature upstream of the convection heating surfaces is ca. 650 °C. The transverse and longitudinal pitch of the tubes in the convection section is large in comparison to the tube diameter. The horizontal arrangement of the convection section also promotes the settling of fly ash, with a beneficial effect on the downstream gas- cleaning system. Fly ash is collected in fly-ash hoppers beneath the heating surfaces and discharged.

Combustion Air Supply. Only a small amount of combustion takes place on the grate itself. The volatile constituents of the fuel escape from the bed of refuse when it is heated and burn on their way through the combustion space. This combustion cannot be controlled when underblast is used. The air flow pattern also governs whether there is a risk of corrosion in the combustion space cooled with boiler tubes. Hydrochloric acid generated by the burning of wastes can attack the tubes if incompletely burned gases (carbon monoxide, CO) are simultaneously present. The supply of combustion air must therefore be sufficient to promote complete combustion of these gases. Grate-fired incinerators are always operated with excess air ($n = 1.5 - 2.0$).

The combustion air must perform the following tasks:

1) Serve as oxidizing agent
2) Cool grate and side walls
3) Prevent slagging in combustion chamber
4) Mix the off-gases and prevent bypassing

A variety of air and air-distribution systems make it possible to achieve these goals.

Primary air is commonly drawn from the refuse bunker. The bunker doors are usually closed, so that a vacuum is set up in the bin region, reducing odors. A filter screen in the intake duct removes coarse entrained particles. A blower delivers the primary air into the underblast zones through the pressure duct. Air preheating is employed when the heating value of the waste drops to the point that predrying is required. Primary air is injected through the grate into and through the bed of fuel, cooling the grate bars and promoting gasification and combustion in the bed.

Secondary air is injected into the combustion space through nozzles to ensure complete combustion of the off-gases, provide intensive mixing of combustion gases, and thus prevent bypassing of unburned gases.

A second stream of air, also drawn from the bunker, is blown onto the side walls of the combustion chamber to keep the flame away from the walls, cool them, and promote the oxidation of the off-gases in the combustion space. If the furnace walls are perforated, the sidewall air can be injected into the combustion chamber perpendicular to the wall over a large area, thus inducing turbulence in the combustion gases so as to break up bypassing jets of reducing gases.

Fly ash is kept away from the walls in this way, preventing formation of deposits (fly ash becomes consolidated if it touches the side walls). Simply cooling the wall, for example by extending the boiler structure downward, does not have the same effect but does lower the wall temperature.

Combustion Control. Waste incineration consists of successive subprocesses. Combustion and steam generation are the main processes and are closely interlinked. The combustion rate and the rate of energy release must be held as constant as possible for uniform steam produc-

tion. The specified steam parameters must be maintained to ensure trouble-free operation.

Boiler and Heat Recovery. Incinerators for household and hazardous wastes can be fitted with steam generators or hot-water boilers. The types of steam boilers used are natural- circulation, forced- circulation, and once-through. Problems with the water recycle stream due to the fluctuating heat delivery have not arisen. The forced- circulation type of boiler used initially has been replaced by the simpler natural- circulation type. Thermal loads per unit heating area are relatively low because of the large volumes of refuse incinerator boilers, so that circulation in the natural- circulation boiler is adequate even with severe load variations.

Older trash incinerators were provided with waste-heat boilers. The refuse was burned in uncooled furnaces and the combustion gases were cooled in downstream heat-recovery units. With increasing heating value of the waste, combustion temperatures have risen to the point that uncooled linings cannot withstand the thermal loads. Cooling was needed for the combustion chamber walls, and so the boiler was placed directly over the grate.

The off-gases must have a residence time of at least 2 s at 850 °C so that all organic species, particularly dioxins and furans, can be completely destroyed.

Turbulence is induced in the off-gases to provide backmixing and also prevent the formation of a reducing atmosphere (CO bypassing) that would promote boiler tube corrosion.

Because of the fluctuating rate of heat evolution, turbulence induced in the off-gases by secondary air injection or deflecting structures is not sufficient by itself. The use of a large excess of air prevents air starvation under all loading conditions that occur. In addition, a rammed lining is present in the lower portion of the cooled combustion space to protect against corrosive attack [305].

A special feature of waste incinerator and boiler installations is the high dust content of the off-gases, since for process engineering reasons the slag softening point must not be exceeded. Precautions are therefore needed to prevent flue-gas contamination.

The combustion gas velocity in the first boiler flue pass is low so that fly ash can settle by gravity. The gas temperature upstream of the convection section must be less than 750 °C, because at higher temperatures the entrained contaminants remain doughy in consistency and tend to build up into deposits that cannot be removed by the cleaning equipment.

For wastes with higher heating values, the combustion gases do not cool to this level in the combustion chamber. An idle pass is therefore inserted in which the gases are completely combusted and homogenized. Fly ash is separated in the flow-reversing zones.

The off-gas velocity must not exceed 10 m/s, since the heating surfaces become fouled at higher velocities. Boilers in waste combustion plants can also be equipped with horizontal passes.

Figure 98. Energy balance for a grate-fired incinerator with flue-dust melting [309]

The boiler must be designed for high temperatures and pressures in order to utilize the energy contained in the waste. Systems have been built for up to 78 bar and 500 °C. These extreme values, however, lead to serious corrosion problems, so that 42 bar and 450 °C should not be exceeded without special justification [305].

The steam generated can be used to generate electricity and/or for district heating. The best efficiency is achieved in a cogeneration arrangement with a pass-out condensing turbine; Figure 98 shows the energy balance for this scheme, including natural gas used to fuse the fly ash.

Off-Gas Cleaning. The thermal treatment of wastes is a complex chemical process. The main reaction, combustion, is an oxidation with the typical combustion products carbon monoxide, carbon dioxide, water vapor, sulfur dioxide, and nitrogen oxides. Along with these compounds, other pollutants are produced; depending on the composition of the waste, these include hydrogen chloride, hydrogen fluoride, dust, heavy metals, nitrogen oxides, dioxins, and furans.

Even though dust-collection and off-gas cleaning technology has reached a high level, further steady progress has been seen since the 17th Federal Pollution Control Regulation (17. BImSchV, see → Air, Chap. 4.3.9.) took effect. The limits set by this regulation led to the addition of denitrification (NO_x removal) and dioxin abatement to treatment systems, and emission levels are now considerably lower than the mandated limits. The recovery of valuable residues is also a goal.

Off-gases are cleaned through a combination of various steps:

1) Dust collection in electrostatic filters or baghouses
2) Wet absorption of acidic species (SO_2, HCl, HF) in multiple scrubbing stages varying in pH
3) Dry sorption of trace organics (such as PCDD/PCDF), heavy metals, and acidic species on activated carbon filters in moving-bed adsorbers and entrained-bed adsorbers combined with bag filters
4) Catalytic reduction of nitrogen oxides (SCR)
5) Noncatalytic reduction of nitrogen oxides by oxidation in the combustion chamber (SNCR)
6) Catalytic oxidation of trace organics such as PCDD/PCDF (OxKat)
7) Thermal treatment (incineration) of pollutant-laden sorbents (residues)
8) Thermal treatment of residues (e.g., pollutant-laden sorbents) from off-gas cleaning
9) Thermal treatment (melting) of slags and dusts
10) Recovery of HCl, NaCl, and gypsum from wet scrubber residues

The requirement profiles for these processes are stated and commercially available equipment is described in [308].

Figure 99. Mass balance for a grate-fired incinerator [309]

Residues from Grate Firing. Combustion of wastes on the grate yields solid, liquid, and gaseous reaction products. Figure 99 presents the mass balance. The literature does not use consistent terminology for solid residues. The following terms are employed here [308]:

1) Slag: solid residue left after waste combustion and not entrained in flue-gases. It is discharged from the end of the grate or falls through the bars between grate steps. This term is not entirely correct since it refers to a mixture of ash, sinter, and slag.
2) Boiler ash: solid residue formed on boiler heating surfaces and falling into hoppers beneath the flue passes.
3) Filter dust: solid residue obtained by dust collection from raw gases and discharged via the hoppers beneath the electrostatic or bag filters.
4) Fly ash: sum of boiler ash and filter dust from electrostatic or bag filters before chemical flue-gas cleanup. The terms "filter dust" and "filter ash" are used as synonyms for fly ash in the literature; boiler ash makes up only a small fraction of the dust (ca. 10 – 20 wt %)
5) Reaction product: solid residue from dry or quasi-dry stack-gas cleanup with upstream dust collection. This product is generated in

the dry or quasi-dry reactor and in downstream dust collection equipment. Concentrated residue from wet stack-gas scrubbing is also referred to as reaction product if the scrub liquor is concentrated in a spray dryer. This reaction product is obtained in the dryer and in the dust collection equipment immediately downstream of it.

The solid residue from dry or quasi-dry flue-gas cleaning without upstream dust collection should therefore be termed a mixture of flue dust and reaction product.

Many publications refer to this mixture as reaction product or dry/quasi-dry residue; however, these expressions do not indicate whether the product contains flue dust.

The quantity and composition of combustion products depend on the makeup of the fuel, the mode of combustion, and the type of stack-gas cleanup.

Table 25. Composition of solid residues from grate firing [309]

Element	Slag	Fly ash
Silicon, wt %	1 – 32	10.28 –16.82
Aluminum, wt %	0.46 – 18.00	6.39 – 9.5
Calcium, wt %	3.32 – 13.4	2.7 – 11.7
Sodium, wt %	0.5 – 6.0	1.2 – 7.5
Magnesium, wt %	0.39 – 1.82	1.2 – 3
Potassium, wt %	0.29 – 2.14	1.9 – 7.8
Iron, wt %	3.71 – 23	2.5 – 4.6
Copper, wt %	0.04 – 0.7	0.07 – 0.2
Chromium, wt %	0.015 – 1	0.02 – 0.32
Nickel, mg/kg	39 – 760	50 – 460
Zinc, wt %	0.05 – 2.1	0.62 – 5.5
Lead, wt %	0.03 – 1.7	0.24 – 5.4
Tin, mg/kg	200 – 1 700	500 – 6 200
Cadmium, mg/kg	0.1 – 79	60 – 1 000
Mercury, mg/kg	0.07 – 7 000	0.2 – 20
Chlorine, wt %	0.03 – 0.63	0.6 – 8.2
Phosphorus, wt %	0.35 – 3.37	0.02 – 3
Sulfur, wt %	0.2 – 0.41	0.6 – 2.97
Fluorine, mg/kg	20 – 1 100	30 – 12 000
Carbon, wt %	0.5 – 5	1.6 – 4.2

Table 25 presents the elemental compositions of solid residues; most of the elements are present as oxides. This form of analysis was chosen because the type of compound (oxide, chloride, sulfate, etc.) cannot be exactly stated for each element and, moreover, cannot be determined by element-specific analytical methods such as atomic absorption spectrometry and ion chromatography. If other elements totaling less than 1 wt % are neglected, the balance consists of oxygen, since all relevant nonoxide compounds (chloride, fluoride, phosphate, sulfate, sulfite, etc.) have already been considered.

Reaction products from dry and quasi-dry flue-gas cleaning are declining in importance because the next generation of refuse incinerators will employ wet scrubbing, so that hydrogen chloride and sulfur dioxide can be separated in different stages and the scrub liquors can be converted to products such as hydrochloric acid, table salt, and gypsum.

9.3.2. Fluidized-Bed Firing [306]

Since it was devised by Fritz Winkler over 70 years ago, fluid-bed technology has found wide use in chemical processing, drying and cooling, gasification, and combustion. It is a proven technique for burning low-grade coals and sewage sludges. More recently it has also come into use for the incineration of household wastes, light fractions of household waste (Fig. 100), and contaminated wood and soil [309].

The fluidized-bed furnace is a lined combustion chamber in the form of a vertical cylinder. In the lower section, a sand bed on a grate or distribution plate is fluidized with air. The waste for incineration is continuously fed into the fluidized sand bed from the top or side.

If necessary, secondary air can be injected into the reaction space above the fluid bed to ensure complete combustion. Oversize material drops out of the lower part of the reactor; ash-laden flue gas exits from the upper part.

Primary air admitted through the perforated bottom thus fluidizes the bed and supports combustion. If the air flow rate in the bottom portion of the bed is substoichiometric, the material for combustion first experiences partial or complete degassing. The waste is then completely burned when secondary air is admitted in the upper zone of the reactor.

As in the grate-fired case, the quality and quantity of the products depend on the nature of the feed, the reactor itself, and the operating conditions prevailing therein.

The input to the process is characterized by

1) The physical properties of the waste and inerts:
   a) Particle size
   b) Particle shape

Figure 100. Flowsheet of the fluidized-bed incineration plant for prepared residential and municipal-type wastes at Berlin-Ruhleben [309]
a) Sand and dolomite bunkers; b) Rotating fluidized-bed incinerator; c) Cyclone; d) Spray dryer; e) Entrained-bed reactor; f) Fabric filters; g) Venturi scrubber; h) SO_2 scrubber; i) Refuse feed; j) Stack; k) Waste bunkers

c) Bulk density
d) Heating value
e) Chemical composition

2) The state parameters of the combustion air:
   a) Density
   b) Viscosity
   c) Temperature
   d) Flow velocity

The reactor is characterized by:

1) Dimensions
2) Shape
3) Air supply type

The operating parameters are the following:

1) Pressure drop
2) Limiting velocities at the fluidization point and the discharge point
3) Depth of the fluid bed
4) Temperature distribution

Fluidized-bed systems have the following features:

1) Complete mixing of solid particles among themselves and with combustion air
2) Resulting good mass and heat transfer between fuel particles and between fuel and combustion air
3) Fixed reactor with no moving parts in the combustion space
4) Possibility of using low-grade fuels with high inert contents
5) Fast process control via throughput
6) Lower air excess than in grate-fired systems; correspondingly small flue-gas streams and low pollutant burdens
7) Possibility of heat removal in bed zone
8) High ratio of hot material to inlet fuel in fluid bed
9) Good ignition due to turbulent motion of fuel; fast combustion due to uniform temperature in fluidized bed
10) Possibility of using inert materials to trap pollutants in the furnace

Because of the special conditions in the fluidized bed, some technical measures differ from those in grate firing:

1) The fuel particle-size distribution must be kept narrow
2) Problems may arise in large-cross-section reactors if the inlet fuel is not adequately distributed over the cross section
3) Solids can be carried out of the bed in an uncontrolled manner (entrainment)
4) The vigorous motion in the combustion chamber can cause erosion
5) Erosion can occur in downstream equipment because of the high dust load in the stack gas
6) The combustion temperature must be held below the sintering point of the fuel so that agglomerates do not form and collapse the bed

For start-up, the cold fluidized bed is heated with gas- or oil-fired auxiliary burners. Once the operating temperature has been reached, the feed material is introduced, and is dried, degassed, and burned in the bed. As combustion proceeds, the particle size decreases until the ash particles are entrained by the upward gas flow and carried out of the bed. Constituents that do not burn and cannot be lifted sink to the bottom of the reactor where they can be discharged.

In combustion operation, the fluidized bed consists of ca. 1 – 3 vol % unburned fuel and ca. 97 – 99 vol % ash. If the amount of ash is sufficient to form a fluid bed, inorganic substances need not be used as bed material.

Ash and oversize can, however, build up even in a fluid-bed incinerator. An excess of these materials can impair the bed, so they are discharged from the lower zone of the fluidized bed.

In comparison with grate-fired incinerators, fluidized-bed units exhibit a higher dust burden in the hot flue gas at the exit from the reactor. This must be considered in designing the flue-gas cleaning equipment.

The discharge behavior is controlled by means of the inlet air velocity, but the discharge of fines with the reaction gases cannot be prevented. The dust burden of this raw gas may be of the order of 20 – 80 g/m^3. Stationary or slow fluidized-bed firing is performed with gas velocities of up to ca. 2.5 m/s, which give a high-density bed with a well-defined surface.

The heat of combustion can be utilized by recovering the sensible heat of the flue gases in a downstream boiler and through heating surfaces in the walls. (The walls can contain membrane tubes or finned tubes as part of the steam-generator circuit). The combustion air in such a unit is split into two streams; primary air fluidizing the bed and secondary air injected into the space above the bed to support complete combustion.

Fluidized-Bed Firing Systems. Fluidized beds are classified as follows:

1) "Stationary" (bubbling or turbulent) fluidized beds (Special case: rotating fluidized beds in single- and two-bed versions)
2) "Fast" fluidized beds
   Circulating beds
   Expanding beds

Figure 101 illustrates the principles on which these firing systems operate.

Figure 101. Fluidized-bed incinerator types
A) Stationary fluidized bed; B) Rotating fluidized bed (special case of stationary fluidized bed); C) Expanding fluidized bed; D) Circulating solids fluidized bed
a) Distributor pipes; b) Ash hopper; c) First boiler pass; d) Distributor plate; e) Air chambers; f) Deflector plate; g) U-beam particle collector; h) Hot cyclone

The stationary fluidized-bed reactor of conventional design is the basic form in fluidized-bed technology. It consists of a cylindrical or rectangular reactor bounded at its lower end by a distribution plate.

Stationary-bed units are less sensitive to feed particle size than other fluidized-bed types; they can accordingly be used for a wide spectrum of particle sizes, but household waste must at least be ground before incineration.

The rotating bed is a special case of the stationary bed in which forced circulation (rotation) improves solids mixing and transport.

Rotating fluidized-bed reactors are made with one or two beds. The combustion chamber is rectangular in cross section. One or two side

walls of the reactor bend inward above the inclined distribution plate to form deflectors parallel to the distributor, thus defining the position of the fluidized bed.

Figure 102. Mass balance for a fluidized-bed incinerator [309]

Figure 103. Energy balance for a fluidized-bed incinerator [309]

Primary air is admitted to the reactor through several air chambers; the flow velocity increases toward the lower end of the distribution plate, so that the bed material there is lifted up against the deflector and made to move toward the higher end of the grate, where the flowvelocity is lower. In this way, the bed is caused to move in an elliptical orbit. In the single-bed variant, the fluid bed thus comprises a rotating "roller"; in the two-bed version, it takes the form of two counterrotating rollers. Bed rotation can be aided by injecting secondary air under the deflector plate or opposite to the restriction.

In contrast to conventional stationary fluidized-bed firing, this design has an additional horizontal fluidizing component. The waste can thus be distributed more evenly and the bed temperature equalized. Components that are not lifted or burned move downward along the inclined distribution plate and exit through an ash discharge at the bottom end of the plate. Ash is discharged continuously or intermittently through a water - cooled screw feeder and classified; the fine fraction is recycled to the reactor.

The bed temperature is ca. 850 °C. For a given heating value, the temperature is controlled by recirculating the stack gases to the primary air system so as to limit the heat generated in the bed. The availability of oxygen is diminished in this way and combustion becomes a two-stage process:

1) Drying, degassing, gasification, and partial burning of fuel in the fluidized bed with primary air
2) Complete combustion in the zone above the bed with secondary and tertiary air

The properties of the rotating fluidized-bed incinerator can be summarized as follows:

1) Rotation of the bed effects good transverse distribution, so that only one feed location is needed
2) High heat-transfer coefficients with large heat-transfer surface areas result in fast heating of the feed
3) The low bed temperature (ca. 800 °C) improves the trapping of acidic pollutants such as SO_2, HCl, and HF in the bed
4) The bed has a uniform temperature distribution because of avoidance of unequally hot spots and avoidance of spotty ignition, smol-

dering (reducing atmosphere), and sintering effects

5) The high degree of turbulence and high velocity of the flue gases in the throat above the bed (flow velocity increases from 2.6 to 5.4 m/s in the throat, then drops to 1.96 m/s in the disengagement space) leads to:
   a) Longer residence time
   b) Complete burnout
   c) Temperatures not exceeding the ash softening point, resulting in absence of sintering effects and no fouling of boiler heating surfaces
6) Splitting the combustion air into primary and secondary air and recirculation of cooled stack gases yields stepwise combustion and thus:
   a) Good controllability
   b) High flexibility
   c) Low NO_x levels
   d) Tolerance to variations in fuel heating value, moisture content, and ash
7) There are no moving parts in the high-temperature zone
8) The design offers high reliability and availability
9) The removal of nonflammable constituents is promoted

Emissions from Fluidized-Bed Reactors. When wastes are incinerated in the fluidized bed, pollutants are emitted in the flue gas, with the solids path, and in the wastewater. Emissions depend on the pollutants introduced with the fuel, the way in which fuel is inlet, the geometry of the combustion space, the reaction properties, the control response of the reactor, and the method used for flue-gas cleaning. Figures 102 and 103 show the mass and energy balances.

The pollutant content of the fuel has the most marked effect on emissions, but the inhomogeneous makeup of wastes means that this effect can only be quantified case by case. The preparation of the feed material for fluidized-bed incineration consists, at least, of grinding to the requisite particle size. This operation makes the combustion behavior more uniform and has a beneficial effect on emissions. Other preparation, such as controlled removal of pollutants, reduces emissions.

The parameters of the bed process also influence emissions such as carbon monoxide, organics, and in part NO_x and solids (fly ash and soot). Stepped admission of combustion air over the reactor height and distributor plate cross section offer some opportunities to optimize the combustion process, for example to achieve complete burning with even a small air excess, to minimize the volume of reaction gases, and to cut down the amount of flue dust discharged.

The carbon monoxide level in the stack gas serves as an indicator of incomplete combustion. The content of CO in the product gas from fluidized-bed incineration can be lowered without increasing the air/fuel ratio if secondary air is admitted in stages.

Sulfur oxides can be trapped in the bed by adding limestone. The binding behavior depends on several parameters, such as the temperature in the fluidized bed and the Ca/S ratio. Widely varying efficiencies have been reported.

The majority of the nitrogen is introduced with the combustion air and reacts with atmospheric oxygen at 1200 °C and higher to form nitrogen oxides. Because incineration temperatures generally lie between 750 and 900 °C, with a maximum of 1200 °C, this reaction does not have to be considered. The NO_x content of the flue gas is therefore due to the largely temperature-independent reaction of fuel nitrogen with atmospheric oxygen. Nitrogen oxide formation increases when limestone is added directly to the combustion space to trap sulfur.

The halogens chlorine and fluorine present in the fuel are almost completely liberated at the prevailing combustion temperatures; they can be partly removed if limestone is added directly to the bed. The optimum temperature range for chlorine and fluorine trapping is ca. 300 °C. Because combustion temperatures in the bed are higher, the expected capture rates for these elements are low; estimates are 50 – 80 % for chlorine and 90 – 99 % for fluorine.

The heavy metals stream is split between flue gases and bed ash. Fluid-bed incineration yields a higher fly-ash content than grate firing, so more heavy metals must be anticipated in the flue dust (depending on the temperature); see Table 26. Fly ash from fluidized-bed combustion must therefore be completely collected.

Figure 104. Flowsheet of a rotary-furnace system for hazardous-waste incineration [308]

1) Solids; 2) Drums; 3) High-heating-value liquid wastes; 4) Pastelike wastes; 5) Low-heating-value liquid wastes

Table 26. Composition of solid residues from fluidized-bed firing (in wt %) [309]

Element	Bed ash	Fly ash
Silicon	47 – 70	
Aluminum	0.14 – 21	
Calcium	5.5 – 13.1	
Sodium	0.8 – 4.0	
Magnesium	0.1 – 2.4	
Iron	0.20 – 0.65	
Zinc	0.0027 – 0.201	
Lead	0.0055 – 0.0812	0.066 – 0.088
Cadmium	1.85 – 5	13.0 – 15.5
Chlorine	0.01 – 0.25	0.3 – 0.6
Phosphorus	0.3 – 1.2	
Sulfur	0.1 – 0.7	0.4 – 0.8
Carbon	0.06 – 0.09	1.6 – 1.8

Emissions by the solids path are divided among these streams (Fig. 102):

1) Bed ash
2) Fly ash
3) Residues from pretreatment

Fly ash entrained in the flue gases is finer-grained than bed ash. Its content of pollutants depends on the time at which the stack gases are cooled. If fly ash is collected prior to flue-gas cooling, it has a pollutant content comparable to that of bed ash. If the flue gases are cooled in the boiler, volatile heavy metals begin to condense here, and under some circumstances new organic compounds begin to form as well; these are predominantly adsorbed on the surfaces of fly-ash particles. The formation of dioxins and furans after cooling of the stack gass (de novo synthesis) is especially relevant. The composition of filter dusts produced in stack-gas cleanup depends on the cleanup method among other factors.

Off-gas cleaning is comparable to the process with grate firing (see Section 9.3.1).

9.3.3. Rotary-Kiln Firing

A rotary kiln consists of a cylinder inclined in the transport direction and lined on the inside with refractory material or a cooled steel shell. The interior of the cylinder can be up to 20 % filled with fuel, which forms a moving bed. Rotation of the furnace about its longitudinal axis turns over the contents and, by virtue of the inclination, causes it to move toward the lower end.

Rotary kilns have been used for around 50 years in the cement, lime, gypsum, magnesite, dolomite, and iron industries. More than 1000 such furnaces are in service.

This type of equipment can be used for incinerating all kinds of wastes: solid, pastelike, and liquid. The furnace is insensitive to variations in the consistency and composition of mixed wastes.

Rotary kilns are especially useful when incineration plants are being designed for future wastes whose composition is not known but must be allowed for, as is particularly the case

with hazardous wastes. Figure 104 is a schematic flowsheet of such an installation. Throughput varies as a function of inlet material, furnace design, and operating conditions.

A rotary-kiln plant (Fig. 105) consists of:

1) Feed devices
2) Air supply and sealing devices
3) Auxiliary firing
4) The rotary shell and liner
5) The drive
6) The afterburner
7) The ash and slag discharge devices

Figure 105. Schematic drawing of an AE & E hazardous waste incinerator [308]

Waste Feeding. Continuous, efficient, and trouble-free operation of rotary kilns requires uniform metering of the waste, particularly the heating value. The mixture of solid, pastelike, and liquid wastes must be controlled so that a homogeneous, viscous melt is formed which forms a coat of slag adhering to the lining and protecting its refractory bricks against erosion and corrosion.

The charging systems of rotary furnaces must be tailored to the properties of the hazardous wastes. The feeders are located at the head end of the furnace (Fig. 106) and are designed to handle the full spectrum of solid, pastelike, and liquid hazardous wastes. Solid wastes are conveyed by a crane or an inclined bucket elevator to the charging hopper; drums are transported by the drum elevator to the charging hopper; pastelike wastes are delivered by pumps and the feed nozzle; liquid wastes arrive via lances; and fuel oil is injected into the rotary furnace via burners. The head end of the furnace can be fixed or movable and has connections for all the above feeding devices.

The most sensitive part of the feed system is the cooled feed chute, which can exhibit cracks at the welds due to thermal stress. Because the chute extrudes about 20 cm into the drum, wastes being conveyed along the rotary furnace can tumble back, wearing the bottom part of the chute.

Some wastes are delivered in drums for operational reasons. The batch size for such wastes is limited because combustion is more uniform, the more uniform the waste feed. At heating values of over 20 MJ/kg, batches should be no larger than 50 kg. If larger drums are fed into the furnace, the heat is liberated so rapidly that even the largest possible quantity of air is insufficient for complete combustion. A charging hole 60 cm in diameter and 80 cm high is sufficient for admitting 50 kg drums. The containers are either incinerated in the rotary furnace along with the waste or are discharged with the slag after the contents have been burned out. These containers are delivered by an elevator and lock; the doors have electrical interlocks so that no connection between the combustion space and the atmosphere exists at the moment when the container drops into the furnace. In newer installations, drum feed is not allowed; drums are emptied and the contents are inlet via burners.

Wastes in pastelike form are delivered to the furnace by thick-matter pumps. Liquid and viscous materials can be mixed in oblique-rotor pumps. Small solid particles cannot damage the pump because of the play between impeller and case, and occasionally they actually are reduced in size. These pumps have delivery heads of about 6 m, so that the waste is thoroughly mixed. This type of pump is proven for paint containing residual solvents.

Severely contaminated liquids can be injected through simple burners, essentially consisting of a double-walled tube with swirl chamber and nozzle; the clear diameter of such a burner is around 10 mm.

Figure 106. Charging of solid, liquid, and pastelike wastes to a rotary furnace for hazardous-waste incineration [308]
a) Solids feed hopper; b) Chute; c) Double gate (lock); d) Drum feeding; e) Lance; f) Multifuel burner; g) Container discharge; h) Wet slag discharge, furnace breeching

Some production residues, such as those from distillation, are liquid at 150 °C but solidify at room temperature. Heated or insulated pressure vessels are used for such materials; these are discharged with nitrogen from the plant system. These wastes cannot be injected through atomizing burner nozzles but flow into the furnace through a 20 mm pipe. Inside the furnace, they move along the hot wall, spread out on the surface, and readily burn. If pastelike materials contain water, droplets of water must not be allowed to impinge the hot lining, because they cause severe stress and premature wear.

Rotary Kiln. The shell of the furnace consists of welded cylindrical rings and is inclined in the direction of material flow. It has a refractory lining. As a rule, the discharge end, which experiences high thermal stress, is a double-walled cylinder with air cooling; the terminal segments are made of heat-resistant cast steel. The furnace shell is sized to be stiff in torsion. The end wall of the furnace is also lined with refractory material (Fig. 107).

Rotary kilns are 8 – 12 m long, in exceptional cases 20 m. They have diameters of 1 – 5 m. The mean combustion temperature is between 800 and 1400 °C, and residence times are ca. 60 min. Afterburners are provided to ensure complete burning of the combustion gases. Throughputs range from 0.1 to 20 t/h.

Wastes, auxiliary fuels, and combustion air are inlet through the feed end. Ash and slag exit the furnace at the other end. The furnace mounting and drive are designed to accommodate the weight of the furnace shell, wastes, and possible deposits inside the furnace. In most systems, the rotation speed can be continuously varied between 0.05 and 2 rpm.

Combustion Air Supply. The air excess is 2.0 –2.5 (to a maximum of 3.0), which is markedly higher than in grate and fluidized-bed furnaces. Rotary kilns are available in cocurrent, cocurrent twin-shell, and countercurrent designs. In a cocurrent kiln, the combustion space is bounded by the feed head, the lining, and the combustion chamber. The movement of waste and slag is in the same direction as the path of combustion air and reaction gas. In countercurrent firing, these two streams move in opposite directions and the breeching with slag discharge forms the "rear" boundary. As a rule, countercurrent operation is possible only if the combustible contents of the waste evolve no pyrolysis gases and the heating value is under ca.

Figure 107. Stress zones in a rotary furnace [308]
a) Furnace shell; b) Refractory lining; c) Discharge ring; d) Terminal segment; e) Cooling air blower; f) Riding ring; g) Trunnion roll; h) Thrust rolls and longitudinal positioning; i) Girt gear; j) Variable-speed drive; k) Steam zone; l) Wastes; m) Combustible matter

8 MJ/kg. Chemical wastes nearly always have large amounts of carbonizable substances and higher heating values. For this reason, countercurrent operation is not common in hazardous-waste processing, though it is used for thermal cleaning of soils. Countercurrent incineration is advantageous for low-heating-value wastes with very high water contents, since the vapors from the drying zone pass directly into the combustion chamber without imposing any stress on the rest of the furnace combustion space. As a result, the wastes are burned more quickly, and a shorter furnace is adequate for complete combustion.

Figure 108. Cross section through rotary kiln mounting [308]
a) Riding ring (welded); b) Furnace shell; c) Lining; d) Burden; e) Thrust roll; f) Trunnion roll; g) Pillow block; h) Base plate; i) Positioning hydraulics; j) Footing

In cocurrent operation, fuel and air are inlet at the cold end, while flue gases and slag exit the furnace at the hot end. If the heating value declines, the ignition boundary moves from the feed end toward the discharge end. The ignition of the fuel can be moved back by turning on the auxiliary burners at the beginning of the shell.

Rotary furnaces are driven by a girt gear, pinion, and variable-speed motor. The rotation speed and thus the residence time of the furnace contents are controlled in this way.

Fuel feed and slag withdrawal must take place at grade level. The rotary furnace is therefore supported on a table some 4.5 m high. The riding rings (Fig. 108) bear the entire weight of the furnace including lining and charge.

If the heating value of the wastes is so low that the material does not ignite and continue to burn, supplementary fuel can be added to the feed or inlet through auxiliary burners. Liquid or pastelike wastes with high heating value can be used for this purpose, but the feed rate cannot be increased indefinitely because this would result in damage to the slag coating.

Lining. Most of the wear in rotary furnaces is due to thermal, mechanical, and chemical stress on the refractory lining. This wear results from the continual, recurrent contact of the charge with the furnace lining. No ceramic material can satisfy all requirements, so the lining must be renewed at regular intervals. Damage to the lining in the furnace feed zone is chiefly mechanical, caused by large and hard objects such as metal-

reinforced pieces of bulky waste, iron drums, and so forth [307].

Thermal stresses due to temperature cycling are produced when moisture is expelled from wastes or when pyrolysis gases are formed at temperatures up to ca. 300 °C.

Bricks with extra thermal fatigue resistance are used in this zone. The lining in the evaporation and melting zone, where the temperature is between ca. 300 and 900 °C, is attacked by solid and liquid compounds, both organic and inorganic, and also as a result of gas and vapor evolution. Hydrocarbon mixtures that ignite early can lead to abrupt and intense flame formation in the bed of material. The thermal stress is highest in the main combustion zone, where there are sporadic temperature peaks up to ca. 1500 °C; in addition, slags and dusts here react with constituents of the refractory material. Attack on the liner is also promoted by infiltration into the brick surface structure when low-melting mixtures are present. If the furnace rotation speed is low, the protective slag coating on the lining can solidify. Wastes that are difficult to ignite or oversize burn in the burnout zone of the furnace discharge end. With the radiant heat from the afterburner chamber, a high temperature profile is achieved so that the slag can be maintained in a thin liquid state. In the breech part of the rotary furnace, the refractory lining can also be attacked by abrasive metal objects in the slag. Especially dense bricks that can resist liquid slag and aggressive gaseous species are used here. The size and form of each stress zone are variable and depend on the operating parameters. The basic suitability and rating of refractories against attack by solid and liquid substances at high temperature are established by the crucible method of DIN 51069. In this test, finely divided slag is allowed to act on a hollowed-out specimen of the ceramic material. Ash melting point and application time are determined or set ahead of time. The slagging resistance is assessed by visual examination of crucible section surfaces.

A single-layer lining is generally 250 mm thick. It is made from double deep-arch bricks or standard arch bricks like those used in rotary cement kilns.

The radial furnace wall is made of ring or bonded brick masonry. Joints are kept narrow and filled with a mortar suitable to the type of brick and forming a chemical – ceramic bond. The periphery of the refractory lining must be stressed to prevent relative motion between the brick courses and the furnace shell. Expansion joints are made to allow for thermal expansion of the refractory in the longitudinal direction. The configuration, size, shape, and sealing of these expansion joints are defined case by case.

A wear-resistant 40 mm underlining of fireclay splits is a good way to enhance the emergency running properties and hold down the temperature of the steel shell. The dam at the head end and the taper in the breeching section are preferably lined with shaped bricks. A steel ring welded in the discharge zone of the drum takes the axial thrust of the masonry. Figure 109 shows a half-section of a rotary furnace with lining.

Figure 109. Partial section of rotary-furnace lining [308] a) Dam; b) Arch bricks; c) Hard fireclay splits; d) Taper; e) Expansion joint; f) Ring masonry; g) Bonded masonry

The design of the furnace lining affects its service life. In general, single-layer masonry is preferred; this is commonly sufficient even for outdoor furnaces. If thermal radiation considerations make an insulating lining indispensable, multiple courses of brick must be placed. Occasionally, two-layer masonry is laid.

Frequent startup and shutdown impairs the durability of the masonry because of the alternating stresses. Masonry repairs are necessary particularly in the transition region from the main shell to the post- combustion chamber, which is the region of maximum temperature and high gas velocity.

Post-combustion. As a rule, the residence time of the reaction gases in the furnace is insufficient for complete burning, so post-combustion chambers are employed. Secondary and sometimes tertiary air is injected into these chambers, and additional burners may also be installed there.

The post-combustion chamber has three key tasks:

1) To ensure complete combustion of the reaction gases
2) To burn liquid wastes injected directly into this chamber through burners
3) To mix the furnace and burner flue-gas streams with the secondary and tertiary air

Flue gases undergo complete combustion when the various gas streams are mixed; theymust be at roughly the same temperature. The gases must therefore have a residence time of at least 5 s in the high-temperature (950 °C) zone.

Slag deposits on the chamber lining may be a problem. If slag particles entrained by the flue gases are deposited on the vertical walls, they will build up, drop down, and plug the burner housing and slag discharge hole. This situation can be prevented with slag-repelling internals and auxiliary burners.

The gas streams can be mixed by installing ceramic mixing screens, which create turbulent flows and thus prevent bypassing. The screens can also effect preliminary removal of dust from the flue gases.

The lower part of the chamber experiences chemical attack by liquid slag droplets carried out of the rotary furnace. This zone is therefore lined with a chemically resistant material such as Alumidon 82. The upper part of the chamber can be lined with corundum, which contains 50 % Al_2O_3. The zone of the first boiler heating surfaces, where the temperature of the flue gases is declining, is lined with A_O and A_I qualities.

Because high-quality masonry is sensitive to frequent alternating thermal loads, continuous operation is recommended. For repairs in the second pass or when waste incineration is briefly interrupted, the temperature of the masonry is held at about 500 °C with fuel oil. To accomplish this, the flue-gas valve is closed and the gases are allowed to escape through an emergency stack at the end of the first pass.

The lining of the afterburner chambers with A_{Ot} bricks yields service lives exceeding 25 000 h. The shape of the post-combustion chamber can be optimized by flow tests; the same is true of the secondary and tertiary air blast points and the blast energy required.

Solid residues from combustion in the rotary kiln take the form of ash or slag, depending on the operating temperature. Ash can be discharged dry or wet; liquid slag must always be discharged via a water bath. When ash is discharged dry, the combustion residues from the furnace fall into a hopper with a water-cooled conveying trough beneath. Dry ash discharge has the advantage that no water is used and no wastewater is generated. Problems can occur in cooling the slag and in sealing the rotary furnace against the atmosphere. The dry ash can be cooled in multiple vibrating trough conveyors, but this requires the addition of water, through water nozzles located at the furnace discharge.

Liquid slag is discharged at high operating temperatures. This improves slag burnout and metal oxides contained in the hazardous wastes are better trapped in inert materials. This mode of operation places severe loads on the masonry, chiefly at the hot end. The furnace shell may be cooled with water to protect the masonry. Liquid slag drops into a quench tank where it is pelletized.

Figure 110 shows the mass and energy balance of a rotary furnace with post-combustion chamber.

9.4. Pyrolysis and Gasification

For some time, the classical incineration process has been faced with competition from several new thermal processing techniques for waste: thermoselect process, pyrolysis – combustion, fixed-bed pressure gasification, and entrained-bed gasification. Figure 111 shows the relationships of thermal processes and their end and intermediate products. Most processes end with a combustion step, in a boiler or an internal-combustion engine.

9.4.1. Principles of Waste Pyrolysis

Organic compounds decompose when heated to give volatile products and coke. The chemical reactions involved are influenced by three factors:

1) Starting materials:
   Chemical composition
   Water content
2) The reactor:

Figure 110. Mass and energy balance for a rotary furnace with post-combustion chamber used for hazardous-waste incineration
1) Waste; 2) Combustion air; 3) Feed end cooling; 4) Shell loss; 5) Tertiary air; 6) Secondary air; 7) Flue gas; 8) Slag; 9) Slag; 10) Wastewater injection; 11) Waste burner; 12) Flue gas to boiler; 13) Radiation loss

Figure 111. Options for thermal treatment of refuse

Vertical-shaft or batch reactor
Rotating tubular or fluidized-bed reactor

3) The operating conditions:
Carbonization (pyrolysis) temperature
Reaction (residence) time

As the reaction time and temperature increase, the composition of the products evolves toward more stable compounds. The pyrolytic degradation of organic materials as a function of temperature proceeds as follows:

100 – 200 °C	Thermal drying, dehydration (physical)
250 °C	Deoxidation, desulfurization; loss of water of constitution and carbon dioxide, depolymerization, onset of hydrogen sulfide evolution
340 °C	Bond breaking in aliphatic compounds, onset of evolution of methane and other aliphatic hydrocarbons
380 °C	Carbonization phase (enrichment of carbon in charge)
400 °C	Cleavage of C – O and C – N bonds
400 – 600 °C	Conversion of bituminous matter to pyrolysis oil or pitch
600 °C	Cracking of bituminous compounds to thermally stable substances (gaseous, short-chain hydrocarbons); production of aromatics (benzene derivatives) by the following hypothetical reaction scheme:
>600 °C	Dimerization of olefins (ethylene) to butylene; dehydrogenation to butadiene; diene reaction with ethylene to cyclohexene; thermal aromatization to benzene and higher-boiling aromatics

The pyrolysis process can be broken down into the following phases, which occur in succession: (1) drying phase, (2) carbonization phase, (3) gas evolution phase.

At temperatures up to 200 °C, physical drying is accompanied by the production of water vapor; this requires much energy (2270 kJ/kg water at 1 bar). If the water content is high, for example because sewage sludge, liquid manure, or liquid hazardous wastes have been added, it may be preferable to insert presses or dryers upstream of the reactor.

Carbonization takes place at 200 – 500 °C. Side groups in high molecular mass organic substances such as cellulose, proteins, fats, and plastics are cleaved. Macromolecular structures are broken down into gases, liquid organic compounds, and solid carbon. In the gas evolution phase between 500 and 1200 °C, the carbonization products are further degraded. Solid carbon and liquid organic products yield the stable gases H_2, CO, CO_2, and CH_4.

The main reactions in the gas evolution phase are the following:

$$C_nH_m \rightarrow x\,CH_4 + y\,H_2 + z\,C \quad (1)$$

$$CH_4 + H_2O \rightarrow CO + 3\,H_2 \quad (2)$$

$$C + H_2O \rightarrow CO + H_2 \quad (3)$$

$$C + CO_2 \rightarrow 2\,CO \quad (4)$$

where *m, n, x, y,* and *z* are partition coefficients.

According to Barniske, higher molecular mass hydrocarbons are decomposed to hydrogen, methane, and solid carbon [310]. Methane reacts with water [311] and is converted to carbon monoxide and hydrogen (synthesis gas). The solid carbon product reacts with water vapor or carbon dioxide to form water gas or generator gas. The pyrolysis of cellulose-containing substances, such as paper, board, wastes from kitchen and garden, and wood waste, is governed by the degradation behavior of cellulose, as illustrated in Figure 112. This process is described by the equation

Figure 112. Cellulose degradation as a function of pyrolysis temperature

$$3\,(C_6H_{10}O_5) \rightarrow 8\,H_2O + C_6H_8O + 3\,CO_2 + CH_4 + H_2 + 8\,C \quad (5)$$

Thermal degradation of polymer materials involves the loss of side chains or substituents and yields products such as H_2O, CO_2, NH_3,

Figure 113. Material and energy balance for low-temperature pyrolysis of residential waste [313]

HCl, H_2S, CH_4, and higher aliphatic hydrocarbons. Polymers can undergo thermal depolymerization to the monomers, while polymer chains can be stochastically fragmented into fragments of various lengths. For example, paraffin wax is formed by heating of polyethylene and polypropylene. These primary decompositions are mostly accompanied by secondary reactions in which the primary degradation products can be repolymerized. At low temperatures, the reactive primary products are partly or almost wholly polymerized to tar. Some of the tar is further converted to gases and coke. At higher temperatures, the primary degradation products have a lower tendency to polymerize [312].

The pyrolysis of wastes generates a varying distribution of gaseous, liquid, and solid products.

Figure 114. Composition of products from residential waste pyrolysis versus final pyrolysis temperature (see Table 27 for inlet composition) [311], [316]
a) Pyrolysis gas; b) Tar/oil condensate; c) Aqueous condensate; d) Solid residues

The end products can be:

1) Fuels or feedstocks (tars, oils, combustible gases)
2) Condensate (water) with dissolved impurities
3) Residues such as coke, metals, glass, and sand

Figure 113 shows schematically the material and energy balance for the pyrolysis of household waste. The products from pyrolysis of household waste are listed in Table 27 according to pyrolysis temperature.

The yield of liquid degradation products such as oils and tars is highest at temperatures below 550 °C. In the medium temperature range, up to 800 °C, the principal products are high-heating-value gases, with smaller quantities of tars and oils.

The yield of lower-heating-value gases is high up to about 1100 °C. When the inlet wastes have a high heating value, solid residues are melted if the temperature is increased to 1400 °C.

Figure 114 shows the product distribution from household waste pyrolysis as a function of final temperature. The quantity of solid residues declines as the final pyrolysis temperature rises to about 500 °C, then remains constant at roughly 0.4 kg/kg waste.

As pyrolysis continues, the content of volatiles in the solid residues decreases, approaching zero at around 500 °C. The carbon content decreases only slightly, to a value of ca. 18 – 20 wt % between 400 and 800 °C. Between 800 and 1000 °C, the carbon content falls to ca. 13 wt %. While the hydrogen content no longer changes appreciably above 800 °C, the CO/CO_2 ratio shifts significantly to the right in accordance with the Boudouard equilibrium, $CO_2 + C \rightleftharpoons 2\,CO$. In tests with waste between 800 and 1000 °C, where the content of organic matter was approximately constant at 34.8 – 39.8 wt % and the moisture content was

Table 27. Household waste pyrolysis products as a function of pyrolysis temperature [314], [315]

Pyrolysis temperature, °C	Pyrolysis gas, kg/kg waste	Acids, condensate, tar	Coke, kg/kg waste	Pyrolysis gas composition, vol %						Coke composition, vol%		
				H_2	CH_4	CO	CO_2	C_2H_4	C_2H_6	Volatile carbon	Bound carbon	Ash
482	0.123	0.611	0.247	5.56	12.43	30.50	44.77	0.45	3.03	21.81	70.48	7.71
648	0.186	0.186	0.592	16.58	15.91	30.49	31.78	2.18	3.06	15.05	70.67	14.28
815	0.237	0.597	0.172	28.55	13.73	34.12	20.59	2.24	0.77	8.13	79.05	12.82
926	0.244	0.587	0.177	32.48	10.45	35.25	18.31	2.43	1.07	8.30	77.23	14.47

between 17.8 and 21.2 wt %, the following distributions were obtained:

800 °C: 23.0 vol % CO_2, 13.0 vol %CO
900 °C: 18.3 vol % CO_2, 20.5 vol % CO
1000 °C: 12.0 vol % CO_2, 29.0 vol % CO

For a roughly constant waste composition, the methane concentration in the pyrolysis gas decreases with increasing process temperature. The CH_4 content decreases from 9.5 vol % at 800 °C to 3.5 vol % at 1000 °C. The formation of oil and tar condensate reaches a maximum between 350 and 500 °C. At higher temperatures, cracking reactions occur and reduce the quantity of tar.

The amount of aqueous condensate depends on the water content of the waste and, to a lesser extent, on the water liberated by degradation during pyrolysis. The quantity of condensate increases up to ca. 300 °C because of the moisture in the waste (32.1 wt %), then remains virtually constant at higher temperatures. It drops if water-gas reactions begin.

The pyrolysis gas mainly consists of simple, low molecular mass compounds. The combustible species are hydrogen, carbon monoxide, methane, and aromatic and higher hydrocarbons. Noncombustible carbon dioxide is produced by the decomposition of oxygen-containing compounds and the combustion of organic compounds. The quantity of pyrolysis gas increases with the pyrolysis temperature, from 70 g/kg household waste at 150 °C to ca. 230 g/kg at 1000 °C. The composition of the gas is shown as a function of process temperature in Figure 115.

Figure 115. Composition of pyrolysis gas versus final pyrolysis temperature [311]

The material balance and gas composition plotted in Figures 114 and 115 are for household waste with the following characteristics [311]:

Lower heating value (inferior calorific value) H_1, MJ/kg	7.2
Water content, wt %	32.1
Ash, wt %	34.3
Carbon, wt %	19.0
Hydrogen, wt %	6.2
Oxygen, wt %	38.7
Nitrogen, wt %	1.1
Sulfur, wt %	0.1
Chlorine, wt %	0.6

The final pyrolysis temperature is thus the governing parameter for the heating value of the pyrolysis gas. While H_2 and CO with their higher heating values (superior calorific values) of $H_h = 12.7\,MJ/m^3$ and $12.6\,MJ/m^3$ (here and in what follows, gas volumes are at STP) are of the same order, the values for CH_4 and C_2H_4 are factors of roughly 3 and 5 higher. If a high-energy-content gas is desired, the pyrolysis reactions must be carried so that large amounts of

methane and higher hydrocarbons are produced [317].

The effect of the process temperature on the gas composition has been confirmed for the pyrolysis of paper (Fig. 116) [318]. While the concentration of carbon monoxide in the pyrolysis gas remains approximately constant with rising temperature, the content of carbon dioxide declines. CH_4 and C_nH_m have their maximum at ca. 550 °C, but decrease above this temperature due to elimination of hydrogen.

Figure 116. Influence of process temperature on gas composition in the pyrolysis of paper [318]

Figure 117 shows how the final pyrolysis temperature of paper affects the heating value of the pyrolysis gas. The highest heating value is achieved at 700 °C. At higher temperatures, the heating value falls off as the CH_4 and C_nH_m concentrations decrease.

Figure 117. Heating value of pyrolysis gas as a function of final temperature in the pyrolysis of paper [318]

9.4.2. Principles of Gasification of Waste

In gasification, an agent is added to convert carbonaceous waste constituents to gaseous fuel and ash or slag. After pyrolysis, a reactive gas is admitted to convert the coked residues to further gaseous products. This is thus a continuation of the pyrolysis process. The residual carbon content of the pyrolysis coke in the red-hot bed is oxidized at temperatures above 800 °C with a substoichiometric quantity of oxygen.

Steam, carbon dioxide, oxygen, or air can be used as the gasifying agent. Like pyrolysis, gasification is both a process in itself and a subprocess of combustion, or of combined pyrolysis and combustion processes such as the Thermoselect process. The products generated by gasification depend on the gasifying agent used (lean gas or synthesis gas). The reaction energy for gasification is produced by partial combustion of the organic material in the gasification reactor. The process is described by the following equations, depending on which of the gasifying agents (oxygen, air, steam, hydrogen, carbon dioxide) is employed:

Oxidation (exothermic):

$$C + O_2 \rightarrow CO_2 \tag{6}$$

$$C_xH_y + (x + {}^1/^4\, y)\, O_2 \rightarrow x\, CO_2 + {}^1/^2\, y\, H_2O \tag{7}$$

$$C + 2\, H_2 \rightarrow CH_4 \tag{8}$$

Boudouard reaction (endothermic):

$$C + CO_2 \rightleftharpoons 2\, CO \tag{9}$$

Water-gas reaction (endothermic):

$$C + 2\, H_2O \rightleftharpoons CO_2 + 2\, H_2 \tag{10}$$

$$C + H_2O \rightleftharpoons CO + H_2 \tag{11}$$

$$C_xH_y + x\, H_2O \rightarrow x\, CO + (x + {}^1/^2\, y)\, H_2 \tag{12}$$

The fuel bed is brought to red heat by partial combustion of the carbon (Eqs. 6 and 7) and reacts with the carbon dioxide formed (Eq. 9). The higher the temperature in the fuel bed, the more carbon monoxide is formed. The CO/CO_2 ratio is represented by the Boudouard equilibrium in Figure 118. The water-gas reaction behaves in a similar way: when steam is mixed with the gasifying air, CO_2 and hydrogen are formed at low

temperatures (Eq. 10) while CO and hydrogen are formed at high temperatures (Eq. 11).

Figure 118. Equilibrium of the Boudouard reaction at atmospheric pressure [319]

Figure 119. Equilibrium of the carbon gasification reaction at 1 bar as a function of temperature [319]

Gasification with hydrogen (Eq. 8) is also exothermic, but this method is not practiced on an industrial scale for reasons of cost. The partial equilibrium reactions (9) and (11) are plotted as functions of temperature in Figure 119 and pressure in Figure 120. The equilibrium gas composition when carbon is gasified with steam is shown in Figure 119. The gasification or reaction rate depends not only on the temperature but also on the porosity, pore diameter, and internal diffusion of the fuel bed. This is why pyrolyzed (i.e., degassed) waste gasifies better than unconditioned waste. The same applies to lumpy material in comparison with loosely piled material. Lumpy (briquetted) material allows a better flow of gas through the fixed bed in the vertical-shaft reactor; at the same time, the formation of gas preference paths–which would lead to incomplete gasification–is prevented. When pyrolysis and gasification take place in a single reactor, the heat required to sustain the dual process is supplied by the partial combustion of carbon in the lower section of the gasification reactor.

Figure 120. Equilibrium of the carbon gasification reaction at 700 °C as a function of pressure [319]

The gaseous products formed in gasification depend on the gasifying agent and the pyrolysis temperature. The gasification products can be classified by heating value:

Lean gas :	$H_1 < 12\,500\,\mathrm{kJ/m^3}$
Rich gas :	$H_1 > 12\,500\,\mathrm{kJ/m^3}$

or according to composition and gasifying agent:
Generator gas (gasifying agent: air)

CO	21 – 30 %
H_2	11 – 18 %
CO_2	5 – 11 %
N_2	47 – 56 %
H_1	5040 kJ/m^3

Water gas (gasifying agent: steam)

CO	40 %
H_2	50 %
CO_2	5 %
N_2	4 %
H_2O	1 %
H_1	12 600 kJ/m^3

Figure 121 shows the equilibrium gas composition for the gasification of carbon with steam.

Figure 121. Equilibrium gas composition in gasification of carbon with steam [319]

A steam – air mixture can also be used for gasification, yielding a "mixed" gas whose composition and heating value fall between those of generator gas and water gas and depend on the mixing ratio of the gasifying agent.

Gasification processes operating at high temperatures (>1600 °C) give a higher gas yield, albeit with a lower heating value, than processes running at moderate temperatures. The heating value of the gases from waste pyrolysis is higher than that from gasification with air:

Pyrolysis gas:	12 000 – 16 000 kJ/m^3
Gas from air gasification:	ca. 5000 kJ/m^3

The latter is of roughly the same order as generator gas from coke gasification (H_1 = 5195 kJ/m^3). If the waste is gasified with oxygen as in the Thermoselect process, the heating value rises to about H_1 = 10 000 kJ/m^3.

Although generator gas has a lower H_1 than pyrolysis gas, the volume of gas per unit mass of waste is larger. The noncombustible substances are converted to ash or slag, depending on the process temperature. As a rule, the melt obtained at high gasification temperatures is pelletized in a wet deslagger. This largely sterile pelletized slag product can be used as aggregate in the construction industry. The solid residues from low-temperature gasification processes are similar to those from combustion, with high ash contents and low carbon contents.

9.4.3. Processes

9.4.3.1. Pyrolysis – Combustion Process

The pyrolysis – combustion process, developed by Siemens KWU for the treatment of household waste [320], combines pyrolysis and high-temperature combustion. The objective is to convert waste into recoverable substances with virtually no residue.

The following process steps are combined: pyrolysis of the feed; recovery of the valuable substances iron, nonferrous metals, and glass/stones from the solid raw material inlet to pyrolysis; and subsequent high-temperature combustion of all the remaining fine carbonaceous residue together with the pyrolysis gas. The organic constituents are degraded, while the noncombustible inorganic material in the residual fines are melted. The melt solidifies in granular form in a water bath; this product is intended for the same uses as the melting-chamber pellets from coal-fired power plants. In the pyrolysis-combustion process, the only residues destined for disposal are those from the flue-gas cleaning system; all other products can be recovered.

Description of the Process. As shown in Figure 122, the pyrolysis – combustion process can be broken down into the following steps:

1) Waste treatment
2) Pyrolysis
3) Treatment of residues

Figure 122. Flowsheet of a pyrolysis – combustion plant [320]

Figure 123. Conversion drum used in the pyrolysis – combustion process
a) Hot gas fan; b) Conversion drum; c) Discharge lock for residues; d) Drum seal suction purge; e) Vibrating cooling trough; f) Collecting trough

4) High-temperature combustion
5) Flue-gas cleaning
6) Energy production

In the treatment step, the waste stored in the refuse bunker is cut by rotary shears, to a maximum size of ca. 200 mm, and then conveyed into the conversion drums by a pusher screw. Sewage sludge can be added in the screw conveyor. The waste mixture is pyrolyzed in the conversion drum; the final temperature is 450 °C. Two homogeneous fuels are produced from the organic content of the waste: conversion gas and fine carbonaceous residue. Both fuels are burned at about 1300 °C in the high-temperature combustion chamber. The conversion drum (Fig. 123) is a rotating kiln supported at both ends. For a throughput of 5 t/h, the drum is 22 m long and

2.8 m in diameter. It is closed at either end with tube sheets into which straight heating pipes are welded.

In drum rotating at 2 rpm and inclined at 1.5°, the average residence time of the waste is ca. 1 h. Flue gas from the boiler downstream of the high-temperature chamber flows through the heating pipes in countercurrent to the waste; the inlet temperature of the gas is 520 °C and the outlet temperature at the end of the drum is 250 °C. The heat from this gas is essentially transferred to the waste by conduction between the waste constituents and the hot surfaces of the heating pipes. If the heating surface is ca. 120 m^2/t, ca. 210 kWh/t is required to heat waste with a moisture content of ca. 25 % to the final temperature of 450 °C.

To maintain reducing conditions in the conversion drum, air leakage is avoided when the waste is charged into it. The pusher screw conveys waste into the pyrolysis drum continuously. The degressive screw pitch provides a small amount of compaction and forms the waste into a plug. This waste plug seals the reaction space of the conversion drum against the surroundings.

The pyrolysis drum is operated at a slight vacuum, while the conversion drum is unpressurized on the hot-gas side. The pressure in the reaction space at the cold end of the drum is nearly atmospheric; a slight vacuum of 2 mbar prevails at the hot end.

All the parts of the conversion drum, from the pusher screw at the cold end of the drum to the rotating shell, the internal heating pipes, and the discharges for conversion gas and residue, are made of steel. Under service conditions, the materials subject to wear exhibit a corrosion rate of less than 0.1 mm/a. Conversion residue and pyrolysis gas are produced from the waste mixture in the conversion drum. A carbonaceous dust is obtained by screening the pyrolysis residue in the residue treatment step. Pyrolysis gas and this dust residue are burned at ca. 1300 °C in the high-temperature combustion chamber (Fig. 124). The temperature in this chamber is controlled by preheating of combustion air and off-gas recirculation. The high-temperature combustion chamber consists of a vertical cylindrical combustion space lined with refractory and having no internals; it is equipped with a multi-fuel burner.

Figure 124. High-temperature combustion chamber used in the pyrolysis – combustion process [320]

The conversion gas is led from the conversion drum directly to the burner. The carbon-containing dust passes through an interim storage stage after residue treatment and is metered into the combustion chamber according to operational requirements. With multistage air feed and the resulting stagewise combustion, NO_x production is minimized. In the first stage, the off-gas temperature is established at ca. 1000 °C by controlled admission of air. The stepwise admission of secondary and tertiary air raises the temperature to ca. 1300 °C in the combustion chamber. The residence time of the off-gas in the temperature range 1000 – 1300 °C is >2 s.

The fine residue has a high content of inert materials, such as sand, glass dust, and abraded porcelain particles. The melting point of this material lies between 1100 and 1150 °C.

At the operating temperature of ca. 1300 °C, a fluid slag resembling glass or basalt is obtained. To protect the refractory lining, the outside walls

of the combustion chamber are slightly cooled. A protective layer of solidified slag is produced at the lining surface temperature of ca. 1050 °C, and the liquid slag drains off over this layer. The service life of the combustion chamber lining is extended in this way. At the bottom of the combustion chamber, the slag flows through a discharge dip tube into the water-filled wet deslagger. The residual carbon content of the slag is <0.1 %.

The hot (1250 – 1300 °C) off-gas exits the high-temperature combustion chamber and flows into the downstream waste-heat boiler. Virtually complete combustion is achieved with the combustion of the largely homogeneous fuels, conversion gas and carbonaceous fine residue, in the high-temperature combustion chamber. Off-gas cleaning resembles the wet scrubbing process downstream of conventional waste incinerators. The principal components of the off-gas treatment system are an electrostatic filter for dust collection, a spray dryer to concentrate the scrubber slurry, a fabric filter to collect fine dust, a two-stage scrubber system, a $DeNO_x$ catalytic unit, and a final cleaning stage.

Figure 125. Mass balance of the pyrolysis – combustion process

An induced-draft fan downstream of the scrubber system generates a slight vacuum throughout the system, conveying the off-gases through the cleaning system. A fixed-bed filter or entrained-bed reactor is used for final cleaning. In the former case, the off-gas flows through a packed bed of open-hearth coke, which adsorbs organic contaminants and heavy metals.

Figure 126. Energy balance of the pyrolysis – combustion process

If an entrained-bed reactor is employed, a mixture of lime and activated carbon is injected into the off-gas stream and then collected in the downstream fabric filter. As the gas flows through this filter layer, residues of organic contaminants and heavy metals are removed. Dioxin and furan emissions after this stage, as well as heavy-metals emissions, are below the limits set forth in the 17th Federal Pollution Control Regulation (17. BImSchV). Ways to separate off-gas cleaning residues into recoverable products are under study.

Hydrochloric acid and gypsum can be produced in a modified off-gas cleaning system with a distillation tower and gypsum dewatering, as in conventional incineration processes.

The steam from the waste-heat boiler can be utilized to generate electricity or in a cogeneration scheme. After plant requirements are met, the surplus electrical and/or thermal energy can

be fed into the distribution grid. Figures 125 and 126 show the mass and energy balances.

Emissions and Products. The fine dust produced in pyrolysis and the conversion gas are burned with a slight air excess. Measurements in a pilot plant have shown operating values to be under the limits of the 17th Federal Pollution Control Regulation by a wide margin.

The pyrolysis – combustion process discharges no wastewater; wastewaters are concentrated in the spray dryer or, if hydrochloric acid and gypsum recovery are included downstream, in an evaporator. The steam is led to the stack along with the stack gases.

The solid products are:

1) Ferrous and nonferrous metals as well as glass and ceramics from residue treatment
2) Pelletized melt from the combustion chamber (see also Table 30)
3) Off-gas cleaning residues, possibly including hydrochloric acid and gypsum

The residue for landfill disposal is 0.1 – 0.3 % of the inlet waste as off-gas cleaning residues, which must be treated as hazardous waste. If hydrochloric acid and gypsum are not recovered, the quantity rises to 2.4 %.

The iron, nonferrous metals, and glass/stone fractions are virtually free of carbonaceous dust. Paints and plastic coatings on metals are removed from the substrate by virtue of the process conditions in the conversion drum, so that ferrous and nonferrous metal scraps, the latter containing over 70 % aluminum, are obtained.

The glass/ceramic fraction can be utilized in civil engineering, highway construction, or landscaping. The pelletized product from the combustion of conversion gas and carbonaceous fines can be used without further treatment.

The pelletized melt and the glass/ceramic fraction from coke processing can be used in bound or unbound subbases for highway construction; in landscaping, for example when noise-protection berms are built or when fill is needed in land reclamation projects; in the construction industry; and as aggregate.

9.4.3.2. Thermoselect Process

Description of the Process. The standard Thermoselect plant consists of two parallel lines each with a capacity of 10 t/h, a common hopper, and a shared process water-treatment system. Modular design permits quick erection of the plant and replacement of components, for example the bottom section of the high-temperature reactor–the component that experiences the most severe thermal stresses.

The process breaks down into the following stages (Fig. 127):

1) Compaction of waste to 10 % of its original volume
2) Pyrolysis in a tunnel-type reactor at temperatures of up to 600 °C
3) Gasification with oxygen in the high-temperature gasifier
4) Discharge of the melt via the homogenization reactor
5) Shock cooling of the synthesis gas to under 70 °C in the quench, with separation of water, dust, and heavy metals
6) Acid wet scrubbing to remove HCl, HF, and heavy metals
7) Sulferox scrubbing to remove sulfur compounds
8) Basic scrub and cooling of gas to 5 °C to remove water
9) Final cleaning of synthesis gas in the gas engine
10) Cleaning of process water, including evaporation

Waste Compaction. The waste, delivered with a low density, is compacted to about 10 % of its original volume in a press. As a result, moisture is evenly distributed in the waste and the residual air content in the compacted waste is reduced. Compaction of the waste promotes heat transport and is a prerequisite for the small dimensions of the waste-treatment plant.

The compactor has a gas-tight connection to the pyrolysis tunnel, afforded by the heat shield. It is mounted on rollers and prestressed with a hydraulic cylinder in order to offset strains due to heating of the pyrolysis tunnel.

The interior of the press–floor, walls, and roof–is lined with 20 mm wear plates of hard metal alloy.

Heat Shield. The heat shield is located between the compactor discharge and the pyrolysis tunnel inlet. It protects the compactor against the temperatures in the pyrolysis tunnel.

Figure 127. Flowsheet of the Thermoselect process [320]
a) Compactor; b) Pyrolysis tunnel; c) High-temperature reactor; d) Shock cooling; e) Surge tank; f) Acid scrub; g) Sulferox scrubbing; h) Gas cooling; i) Activated-carbon filter; j) Solids separation; k) Neutralization, flocculation, precipitation; l) Sedimentation, filtration; m) Reverse osmosis; n) Evaporation

Pyrolysis Tunnel. The pyrolysis tunnel (Fig. 128) located between the heat shield and the high-temperature reactor, is a double-walled reactor, rectangular in cross section. At intervals of roughly 5 – 10 min, waste is pushed through the interior of the tunnel in steps. Heat is supplied from outside through the inner wall of the tunnel, the space exterior to this wall being heated in countercurrent to the waste. The heating gas is heated in a combustion chamber by burning synthesis gas generated in the process.

Figure 128. Thermal section of a Thermoselect plant [319]
a) Compactor; b) Heat shield; c) Pyrolysis tunnel; d) High-temperature reactor

The compacted masses of waste in the pressure-tight pyrolysis tunnel (similar in design to a pusher furnace) form a gas-tight plug. In the externally heated pyrolysis tunnel, the wastes are dried and then pyrolyzed as they pass along. In addition, heat is supplied by radiation from the downstream gasification reactor.

The pyrolysis tunnel is tapered in the process direction and has gas-discharge ducts on the inside. In this way, material transport and the removal of pyrolysis gas in the process direction is promoted. The pyrolysis tunnel is sealed gas-tight to the compactor at one end and is open to the high-temperature reactor at the other. It is mounted on rollers to compensate for thermal stresses. The lumpy pyrolysis coke consists of partly pyrolyzed organic material together with inorganic mineral and metallic residues.

High-Temperature Reactor. The partly pyrolyzed waste at ca. 600 °C, is discharged from the pyrolysis tunnel into the gasifier (Fig. 128) with the introduction of new packets of waste. The pyrolysis gas from the pyrolyzer also flows into the high-temperature gasifier.

The pressure generated by outgassing causes the briquetts to disintegrate, and the fragments are spread through the reaction space. In this way, an irregular, gas-permeable bed is created. The depth of the bed is held constant by process control of the gasification reactor.

The gasifier is a vertical-shaft reactor with an inlet opening for the partly pyrolyzed material and a gas discharge in the upper section for removal of synthesis gas. The reaction space is

bounded below by a base through which the melt is discharged to the homogenization reactor and thence to the water bath for pelletizing. The reactor has refractory lining, insulation, and cooling as appropriate to the operating temperatures.

In the lower section it is fitted with a ring of burners supplied with synthesis gas or natural gas and, in normal operation, with preheated oxygen. The oxygen serves as gasifying agent, reacting exothermically with the carbon content still present in the lower part of the bed to form carbon dioxide. The ascending CO_2 is reduced to CO as it passes through the carbon-containing bed. Ideally, this process goes to the Boudouard equilibrium.

The water-gas reaction takes place in the presence of an excess of hot water vapor, yielding carbon monoxide and hydrogen. Organic compounds are cracked.

Due to the exothermic gasification of carbon, the temperature in the lower section of the gasifier is ca. 2000 °C. All metallic and mineral constituents of the waste are therefore melted. The gases ascending in countercurrent in the reactor bring about residual pyrolysis in the top part of the bed. The most important parameters for the processes occurring in the gasification reactor are the melt flow, the height of the column of material in the reactor, and the outlet temperature and composition of the synthesis gas.

The temperature needed to maintain a fluid melt is generated by the combustion of carbon with oxygen. If this heat is not sufficient, gas can be supplied through the burners. If the synthesis gas temperature falls below 1200 °C at the reactor outlet, the oxygen quantity can be adjusted. Part of the inorganic matter vaporized by the high temperatures in the bottom of the reactor and entrained in the synthesis gas con-denses on the reactor walls and flows downwards.

Above the outlet of the pyrolysis tunnel is the stabilization zone, where gases from pyrolysis and gasification are mixed and heated to at least 1200 °C. Chlorinated and long-chain hydrocarbons are destroyed. After a residence time of ca. 4 s, the gas exits the high-temperature reactor and passes on to the shock cooling (quench) stage.

Homogenization Reactor. The melt from the high-temperature reactor flows into the melt bath of the homogenization reactor. This melt can contain carbon and impurities, which are gasified if the partial pressures of oxygen and water vapor are sufficiently high. The combined-fuel burners are arranged above the melt, pointing opposite the flow direction, so as to induce thermal turbulence in the melt. By virtue of its higher density, the metallic melt flows along the reactor bottom under the mineral melt. The melt flows over the discharge sill into a refractory-lined trough leading to the granulation system.

All gaseous reaction products flow into the high-temperature reactor.

Synthesis Gas Cleaning. Pyrolysis in the tunnel reactor and gasification with oxygen in the gasifier generate ca. 1000 m^3 of synthesis gas per tonne of waste. The synthesis gas exits the reactor at ca. 1200 °C. Its main components are carbon monoxide and hydrogen, which can be used for energy production, as well as water vapor and carbon dioxide. The gas is comparable with synthesis gas from other pyrolysis and gasification processes (see Table 28).

Sulfur inlet with the waste is present in the synthesis gas mainly as H_2S. Ammonia is unstable at 1200 °C, decomposing to nitrogen and hydrogen. Metals and metal compounds may also be present in gaseous form, depending on the vapor pressure.

The gas cleaning system has the task of removing these contaminants and collecting solid particles (ash, soot, and graphite). This system consists of the following units (Fig. 127):

1) Gas quench
2) Surge tank
3) Acid scrubbing
4) Sulferox scrubbing
5) Gas cooling
6) Adsorption

1) Gas quench: The crude gas from the gasifier flows into the first stage of the two-stage gas quench, where it is cooled from ca. 1200 °C to <90 °C against water. The purpose of this quench is to prevent the de novo synthesis of dioxins and furans that takes place when gases containing chlorine and carbon are cooled slowly.
   The crude gas flows through the quench radially; well-defined quantities of water are delivered from a radial ring slot. The formation of deposits of solid particles is prevented by a water-cooled ram.

Table 28. Composition of Thermoselect synthesis gas compared with other gasification processes

	Generator gas	Water gas	Thermoselect
CO	21 – 30 %	40 %	32 – 47 %
H_2	11 – 18 %	50 %	29 – 37 %
CO_2	5 – 11 %	5 %	19 – 29 %
N_2	47 – 56 %	4 %	ca. 2 %
H_2O		1 %	ca. 1 %
H_1	5040 kJ/m^3	12 600 kJ/m^3	up to 10 000 kJ/m^3
Gasifying agent	air	steam	oxygen

2) Surge tank: The crude gas after removal of solids and acidic constituents flows into the surge tank, which safeguards the downstream unit against overpressure. This protection consists of a submerged branching, which directs gas to the flare if the pressure becomes excessive.
3) Acid scrubbing: The cooled crude gas enters the rotary scrubber, where water is sprayed in to eliminate dust and soot particles as well as salt and acidic species such as HCl and HF. The water discharge from the quench and rotary scrubber dips into the sedimentation vessel. Hydrochloric acid is metered into the scrubber from a supply tank to hold the pH constant.
   In the second scrubber, of packed-tower type, additives are introduced to eliminate the residual fine solids with the acidic contaminants. The process water is led through a filter to the water-treatment stage. The filter cake is recycled to the waste feed end together with the solids from the sedimentation vessel.
   The sedimentation vessel consists of three chambers separated by overflow weirs. In the first, coarse solids (also containing carbon) settle out. A bucket elevator conveys the solids from the chamber into circulating containers, which carry the solids to the waste inlet end. In the second and third chambers – the second being provided with lamellae to promote sedimentation – finer particles settle out and are pumped to the water-treatment system for filtration.
   This sedimentation vessel also serves as a water supply tank for the quench water loop and acid scrub.
4) Sulferox scrubbing: Hydrogen sulfide in the gas is converted to sulfur and hydrogen in the Sulferox scrubber. For this purpose, the gas is led through a water-irrigated packed tower in cocurrent with iron chelate.
   The trivalent iron in the chelate is reduced to divalent iron by H_2S with the formation of elemental sulfur and hydrogen. A substream is withdrawn from the water loop and pumped into the regeneration stage, whereby the heat of reaction is removed via heat exchangers.
   Divalent iron in the sulfur-containing iron chelate solution is oxidized to trivalent iron by admitting air to the regeneration/sedimentation tank. The sulfur sinks downward and forms a sulfur-chelate mixture, which is pumped to a vacuum filter that continuously delivers a sulfur cake.
   The filtrate is split into two substreams, of which one is pumped back to the regeneration tank while the other goes to the collecting tank of the process-water treatment system.
   The recycle from the regeneration tank is fed back to the scrub-liquor loop of the Sulferox scrubber. Water mist is eliminated from the gas by a packing; the water goes to the cooling stage.
5) Cooling: Any traces of heavy metals and water are eliminated by two-stage low-temperature drying. The gas stream is cooled to 36 °C against cooling water in the first stage, to 5 °C against chilled water in the second. The elimination of water increases the heating value of the synthesis gas.
   After mist elimination, the gas is next reheated against warm water in a heat exchanger.
6) Adsorption: The remaining gaseous contaminants are adsorbed in an activated coke filter. The spent coke is recompacted with waste and pyrolyzed. The purified synthesis gas can be employed for heating the pyrolysis

tunnel or for energy production in an internal combustion engine or gas turbine.

The mass and energy balances are shown in Figures 129 and 130.

Process-Water Treatment. A water treatment unit is provided for treating all waters from gas cleaning (Fig. 131). Two main wastewater streams must be distinguished: the virtually solids-free main stream from gas cooling and drying, and the solids-laden stream from the sedimentation tank, into which wastewater from the quench and acid scrubbing stages have been collected.

The solids (graphite and soot particles, heavy metals, and salts) are sedimented in the sedimentation tank. The purified water is pumped back to the gas cleaning unit.

All process water is subjected to treatment in the following stages:

1) Neutralization and precipitation
2) Flocculation and sedimentation
3) Microfiltration
4) Reverse osmosis
5) Evaporation

1) Neutralization and precipitation: In this stage, the pH of the solids-free wastewater is adjusted with NaOH in a stirred tank. The pH for subsequent precipitation of heavy metals is established in a second stirred tank. Heavy metals are precipitated from the basic wastewater by the addition of sodium sulfide in a stirred reactor. Experience with coal gasification shows that heavy-metal complexes need not be anticipated from gasification in the high-temperature reactor or from gas cleanup.
   The outlet wastewater stream goes to a static mixer, where iron chloride and flocculants are added.
2) Flocculation and sedimentation: This stage of the process consists of a stirred tank for separation of further heavy metals by flocculation and a lamellar classifier for the removal of product solids by sedimentation. The clarifier discharge is pumped to microfiltration.
   The sedimented metal hydroxide slurry is transferred to the static thickener and thence to the recessed-plate filter press. The filter cake mainly consists of metal hydroxide sludge, sulfides, fluorides, and carbonates, and must be disposed of as hazardous waste.
3) Microfiltration: After sedimentation, the finest solids are separated from the wastewater in two alternately operated sand filters. While one filter is in service, the other is being backwashed.
   Filtrate from the downstream collecting tank is used as backwash water. The solids-laden backwash liquor is pumped back to the second stirred reactor of the precipitation stage. Because the fine particles form conglomerates in the sand filter, they are removed by flocculation and sedimentation downstream of the precipitation stage.
4) Reverse osmosis: Two-stage reverse osmosis is used to concentrate the salt solution, which contains mainly chloride and a small amount of sulfates. Part of the first-stage permeate, depending on quality, is recycled to maintain a constant salt load in the second stage. The second-stage permeate is used for cooling, together with the condensate from the evaporation unit. The concentrated salt solution is led to the buffer tank of the evaporator.
5) Evaporation: The solids-free wastewater flows from the buffer tank into the pump suction tank of the evaporation unit, from which it is fed into the forced circulation of the two parallel evaporators. The two evaporator loops each consist of the evaporator proper, the stripper, and the circulation pump.

In the evaporator, the salt solution is heated to its boiling point and part of the liquid evaporates. This portion of the water is separated as vapor in the stripping section. The pump circulates the salt solution until it reaches its final concentration. The solution is then collected in a stirred tank. The forced circulation limits the de-position of salt in the apparatus and piping. An antifoam is added to prevent foaming in the stripping vessel.

After the evaporator, the salt solution is further concentrated in a hydrocyclone and a centrifuge, put into containers, and disposed of externally. The condensate from the evaporator vapor is collected and reused in gas cleaning. The salt-laden wastewaters from the cyclone and centrifuge are recycled to evaporation.

Emissions and Products. The products of the Thermoselect process are synthesis gas, mineral substances and metal pellets, sulfur, metal hydroxide sludge, and salt from process-water treatment. Emissions depend on the way in which the synthesis gas is utilized.

Synthesis Gas and Gas Engine Exhaust. Most of the energy content of the wastes is used in the production of synthesis gas. The principal components of the synthesis gas are listed in Table 28. The purification of the synthesis gases effectively reduces the levels of contaminants. Table 29 lists the contaminants present in the synthesis gas and the exhaust from the gas engine.

Regardless of the combustion process used (internal combustion engine, industrial heating, steam), the impurity concentrations found in the purified synthesis gas are such that the anticipated emission values are markedly less than the limits mandated by 17. BImSchV.

After cleaning the synthesis gas contains no significant concentrations of substances whose combustion could lead to the formation of polychlorinated hydrocarbon compounds.

Figure 130. Energy balance of the Thermoselect process

Figure 131. Flowsheet of wastewater cleaning in the Thermoselect process [320]

The content of nitrogen oxides in the off-gas from synthesis gas utilization is essentially controlled by the combustion conditions. The main components, carbon monoxide and hydrogen, lead to an off-gas with low NO_x levels.

Glassy Mineral Substances. The Thermoselect process with optimal energy utilization yields directly usable glassy mineral products with no interruption of the material and energy streams. Suitability of these materials for use as, for example, concrete aggregate has been established in an expert opinion of the Thuringian TÜV [320], [321]. The residues contain sufficient amounts of mineral-forming substances to give eluate-resistant materials.

With regard to the quality of the mineral products, the low residual carbon content of 0.05 – 0.12 wt % and the stable trapping of heavy metal traces are of key importance.

The basalt-like state and the high degree of inertness are responsible for the good elution parameters, as listed in Table 30. The measured contaminant levels in the eluate are low, so that this pelletized product meets the standards of the TA Siedlungsabfall. According to opinions issued by the Rhine-Westphalian and Thuringian TÜV, this material can be deposited or used without special precautions.

The following options exist for the use of the pellet product:

1) In ground form, directly at the construction site (similarly to fly ash from coal-fired plants), as partial replacement for cement in concrete preparation; also as a filler (>90 µm) for asphalt
2) In ground form, with the addition of blowing agents, for the fabrication of expanded granular material with good insulating properties
3) As a blasting medium for metal surface finishing
4) As an aggregate for concrete with partial or complete substitution of one aggregate fraction
5) As a frost-protection layer (subbase material) for highway construction or in bituminous road surfacing
6) For manufacture of mineral fibers directly from the melt

Metal Alloy. The metal produced in the Thermoselect process is low-alloy iron (>90 wt % Fe) with the following principal alloying elements [322]: copper (5 wt %), nickel (0.6 wt %), chromium (0.3 wt %), tin (0.4 wt %), phosphorus (2 wt %).

The concentrations of environmentally relevant elements such as thallium (0.01 wt %), cadmium (<0.001 wt %), lead (<0.08 wt %), mercury (<0.00001 wt %), and arsenic (<0.05 wt %) are low. This metal can be recycled to metallurgical processes, for example as a raw material for copper winning.

Development of the Process. In the 1980s the original idea of the Thermoselect process was compacting wastes to improve landfill utilization. Because the compacted waste packets were unstable, the possibility of thermal surface treatment was investigated [321].

The principal developmental stages of the Thermoselect process are summarized in the following:

1989	Carbonization behavior as a function of pressure, temperature, time; material suitability (10 kg/h)
1990	Carbonization and degassing behavior with compactor, pyrolysis in pressure pipe; testing of melt behavior, instrumentation, and various gas cleaning variants (250 kg/h)
1991	Carbonization and degassing behavior in various pressure- and temperature-stable pusher furnaces up to 20 m long and with cross section of 0.225 m^2, coupled with compactors; testing of gasification behavior, test of lining; burner development, including safety aspects and quick-replacement device; material stability; instrumentation; product quality (1000 kg/h); development of overall concept of full-scale pilot plant and preparation of construction documentation (4200 kg/h)
9/1991	Start of plant construction
12/1991	Completion of building
3/1992	Completion of main installation tests on stable melt discharge, effect of level; tests of safety systems; startup and shutdown conditions; charging control; testing of stability of compactor/tunnel, tunnel/high-temperature reactor, and high-temperature reactor/quench interfaces; continuous operation, reaction to load variations; optimization of gas cleanup, optimization of internal combustion engine operation
6/1992	Sequestration ordered by government authorities
10/1992	Commissioning of entire plant after final installation of evaporator unit; regular plant operation on license basis of 4200 kg/h
1/1993	Start of plant evaluation by Italian, Swiss, and German bodies
4/1993	Dismantling of main modules and inspection by independent bodies to assess stability of individual components and availability
11/1993	Completion of 12-month main testing, including test of a 1.2 MW gas engine
12/1993	Evaluation of experience to define standard Thermoselect plant
4/1994	Approval for continuous operation; restart

[a] DEV-S 4 = Deutsches Einheitsverfahren S 4. [b] SET = Schweizer Eluat-Test.

Several aspects of plant operation, especially emissions and product quality, and of plant safety were assessed by independent experts. The safety of the pilot plant, in particular with regard to fire and explosion protection, was determined by Italian licensing authorities.

Tests in the large pilot facility led to optimization of the following points:

1) Improved cooling capacity in the quench water system
2) Use of an improved lamellar classifier system and discharge of solids from the quench loop for recycle to thermal treatment
3) Integration of direct sulfur removal, including regeneration of the Fe(II)/Fe(III) complex
4) Integration of an internal combustion engine/generator system for power generation

The capacity limitation of 4.2 t/h specified for the erection of the Thermoselect plant will remain in place because all engineering equipment selections and the design of the gas and water cleanup units, including evaporation, were based on this figure for approval-related reasons.

9.4.3.3. Noell Conversion Process

Description of the Process. The Noell conversion process combines thermal conditioning (pyrolysis) with an entrained-bed gasification stage. The heterogeneous starting materials (e.g., residues from treatment of household and hazardous waste, electronics scrap, and automobile scrap processing) are homogenized into coke in the pyrolysis step, then ground. These intermediate products are inlet to entrained-bed gasification together with the pyrolysis gas and the collected condensates. Residues in dust form, such as dried and ground sewage sludges, pulverized plastics, waste oils, pumpable sludges and slurries, paint residues, and contaminated liquids, can be fed directly to the entrained-bed gasifier. Figure 132 illustrates the design of the Noell conversion process.

Waste Pretreatment. After size reduction in rotary shears to <50 mm, the wastes are either inlet directly to pyrolysis or, depending on their moisture content, to a preliminary drying stage. The purpose of this step is to improve the thermal efficiency, especially where water contents are high. The waste heat from the process is used.

Pyrolysis. The pyrolysis stage is based on experience with the hazardous-waste pyrolysis plant at Salzgitter, Germany, in which a rotary kiln with a diameter of 2.80 m and a length of 28 m was tested. Figure 133 shows the construction of the pyrolysis stage.

Figure 132. Flowsheet of the Noell conversion process [323]

Figure 133. Flowsheet of the pyrolysis section of the Noell conversion process [323]
a) Quench cooler; b) Final cooler; c) Decanter 1; d) Decanter 2; e) Gas tank

Residual waste is discharged through a lock system, blanketed with nitrogen to exclude oxygen. A pusher screw below the lock system compacts the waste and charges it to the pyrolyzer. The compacted plug prevents the escape of pyrolysis gas through the charging system.

In the rotary kiln, the waste is heated to a temperature between 650 and 750 °C under air exclusion. The waste is pyrolyzed, yielding crude pyrolysis gas and pyrolysis coke as intermediate products; these are forwarded to intermediate treatment.

The pyrolysis unit is indirectly heated with purified synthesis gas from the gas cleaning process. Heating the pyrolysis kiln requires 20–25 % of the clean gas produced. The use of low-temperature burners to limit NO_x formation makes it possible to meet the standards of the 17th Federal Pollution Control Regulation (17. BImSchV).

After separation of the pyrolysis coke, the crude pyrolysis gas discharged from the coke separator at a maximum temperature of 500 °C is cooled to 70 °C against cooled recirculating product. The various liquid hydrocarbons, as well as water and coke dust if present, are eliminated here. The separation of a solids-poor fraction for recycling takes place in a downstream decanter. In a second cooling stage working on a similar principle, the pyrolysis gas is brought to 30 °C before going to gas storage and compression. Utilization of pyrolysis gas in the entrained-bed gasifier increases the flexibility of the system to handle strongly fluctuating ash levels. At the same time, hydrocarbons, and particularly also chlorinated hydrocarbons, in the synthesis gas components are decomposed. The slurry product from the two decanters is also inlet to the entrained-bed reactor.

Treatment of Pyrolysis Products. The pyrolysis stage is followed by separation of pyrolysis coke, pyrolysis gas, and pyrolysis vapors and treatment of these products for use in the entrained-bed gasifier.

First, the pyrolysis coke is cooled. Next, ferrous and nonferrous metals are removed by magnetic and eddy current separators, and the coke is ground to <0.5 mm. The separation of inert materials is not carried out. The ground pyrolysis coke is delivered to the gasification burner by a pneumatic conveyor.

The gas and vapor products from pyrolysis are quenched, yielding an oil – water – dust slurry that contains the readily condensable species. The gas is then indirectly cooled to separate water and condensate. The slurry and the pyrolysis gas are separately forwarded to the gasification reactor by pumps and compressors.

Because pyrolysis and gasification take place in separate apparatus, the two substages can operate independently if intermediate storage is provided for the products.

Entrained-Bed Gasification. The intermediate products are fed to the entrained-bed gasifier, where they are converted to crude synthesis gas with technical-grade oxygen. The gasifier consists of a cylindrical reaction chamber bounded by a water-cooled pipe wall. The gasification burner is located at the top of the reaction space and delivers the material for gasification and the oxygen, and maintains a pilot flame generated by a combustible gas of external origin (natural gas, digester gas, pyrolysis gas) or recycled clean gas. Ignition and monitoring devices are integrated in the burner (Fig. 134).

Figure 134. Entrained-bed gasifier used in the Noell conversion process [323]

The gasification feed, in dust form, is delivered by a pneumatic metering system consisting of a supply bin and pressure locks operated in alternation. Inert gas is injected to bring the material to the plant pressure of 25 bar. The material then flows by gravity to a special metering vessel. Injection of an inert conveying gas into the bottom of the metering vessel fluidizes the dust in a localized manner, and in this state (dense suspension in conveying gas) it is delivered to the gasification reactor burner by means of a pressure difference.

In the reactor, the substoichiometric quantity of oxygen and the carbon from the organic feed materials are converted to CO_2 in a flame reaction. The CO_2 is then reduced to CO according to the Boudouard reaction. In a parallel process, water is cleaved down by the water-gas reaction at final temperatures of 1400 – 1700 °C, so that a crude synthesis gas, rich in CO and H_2 and

free of hydrocarbons, is produced. This strongly reducing gas is led downward into the quench.

Mineral constituents of the feed material form a slag film, which flows down into the quench space via the reaction space wall, which is protected by a thin layer of a special rammed mass and solidified slag. The gas, saturated with water vapor, exits the quencher at the side, while the granulated product is collected in the water bath and discharged through a feeder.

The quantity of synthesis gas produced is 0.7 – 1 m^3/kg of waste and sewage sludge, depending on the water and ash contents in the feed. The purity of the technical oxygen can be adapted to the intended use. The oxygen ratio is chosen between 0.3 and 0.6 so that the exit temperatures of the crude gas ensure continuous flow of the glassy melt without supplementary heating.

Synthesis Gas Cleaning. The crude gas, saturated to the dewpoint after quenching, is next subjected to the following purification stages:

1) Venturi scrubber to remove dust and salt
2) Condensation of water vapor
3) Desulfurization (removal of H_2S and COS)
4) Optional processing to synthesis gas for methanol synthesis (Fig. 135)

To remove dust and salt, the crude synthesis gas is passed through two Venturi scrubbers in series. Metal oxides can also be precipitated as metal sulfides in this stage by using hydrogen sulfide. The wastewater from these stages is fed to quenching.

At the plant pressure of 25 bar and a saturation temperature of 205 °C, the crude synthesis gas has a steam content of 65 %, so that a low-pressure steam (about 6 bar) for district heating or internal use can be obtained by cooling. Condensation of the water vapor when the gas is cooled also removes any remaining traces of salt and fine solids. This is a prerequisite for the downstream desulfurization step.

Sulfur is present as hydrogen sulfide (ca. 90 %) and carbonyl sulfide (ca. 10 %). Oxidation processes involving iron chelate solutions or adsorption processes involving activated coke or metal oxides are employed to remove this sulfur. After this stage, the clean synthesis gas is suitable for use as a feedstock or fuel. Depending on the use, the gas may be treated in a variety of ways, for example by crude gas converting to establish a desired H_2/CO ratio in a feedstock gas.

By recycling the quench and scrub liquors and the condensate produced by gas cooling, the quantity of process wastewater requiring purification can be restricted to the amount entering with the residues and wastes. The process can thus be operated without generating wastewater.

Crude Gas Scrubbing. Like the use of synthesis gas as a feed to catalytic synthesis processes, its use to generate electricity, whether in gas turbines or internal combustion engines, requires the complete removal of fine dust, volatile metal oxides, and salt mists. The desulfurization stage downstream of the crude gas scrubbing can tolerate only limited concentrations of these contaminants. If gasification is performed under pressure, the use of Venturi scrubbers followed by a heat-recovery boiler (Fig. 135) offers a fairly simple solution. When large amounts of water vapor are condensed from the crude synthesis gas in the heat-recovery step, even small aerosol particles are trapped in the condensates, the larger particles having been removed in the Venturi scrubbers. The scrubbing liquor also dissolves part of the hydrogen sulfide. This is a prerequisite for the precipitation of volatile heavy metal oxides as heavy metal sulfides, which are insoluble and not classified as toxic.

Desulfurization. The gasification of residues and wastes under pressure makes it possible to remove sulfur down to the level of 1 – 10 mg/m^3. This is an order of magnitude better than the 50 mg SO_2/m^3 limit set by the 17th Federal Pollution Control Regulation. What is more, the volume of the gas stream is much smaller. These gains are possible only if carbonyl sulfide is eliminated by catalytic hydrolysis. The removal of hydrogen sulfide on activated coke or carbon is a simple technology and one proven over decades. If the stoichiometric quantity of oxygen for oxidizing H_2S to elemental sulfur is provided, the oxidation process goes to completion on the internal surface of the coke, and elemental sulfur is deposited there at the same time. It is desirable to use a moving bed in the adsorber, with fresh coke inlet at the head and the crude gas led in countercurrent. The spent activated coke is withdrawn at the bottom and recovered.

In the Sulferox process, hydrogen sulfide is oxidized by Fe^{3+}, dissolved as an iron chelate. The crude gas flows through a bubble-column

absorber before leaving the downstream separator as cleaned synthesis gas. The iron reduced to Fe^{2+} by oxidation of hydrogen sulfide is passed to the regenerator and reoxidized to Fe^{3+} with air. It can then be recycled to the absorber. Elemental sulfur is separated in a drum filter and washed.

Wastewater Treatment. The type of process wastewaters inlet to treatment depends on the design of the circulation streams (see Fig. 136):

Stream 1:	Wastewater from granulate product discharge (ash removal)
Stream 2:	Venturi scrubbing liquor
Stream 3:	Excess water from quencher

For the utilization of heat internal to the process, the hot (205 °C) scrubbing and quench liquors are first used in the evaporator. After the water from granulate discharge is added to ensure optimal closed-circuit operation and minimize the quantity inlet to the wastewater treatment system proper, solids are mechanically removed by a hydrocyclone in a first process step. The solids-rich stream from this stage contains essentially slag fines. It is dewatered in a belt-type filter press and then fed back to the gasification unit to be incorporated in the granulated product. In the second process step, milk of lime is added to precipitate sparingly soluble salts. Any heavy metals still in solution at this point are collected by a selective precipitating agent.

The precipitated salts, together with solids not removed in the hydrocyclone and soot particles, coagulate in the flocculation stage and are removed by gravity in the lamellar classifier. The product slurry is thickened, flocculant is added, and the slurry is dewatered to >35 % dry solids in a recessed-plate filter press. After precipitation/flocculation, the wastewater is in such a condition that much of it can be reused in the gasification process. Wastewater not returned to the process is subjected to two-stage cyanide oxidation, in which hydrogen peroxide is used as the oxidizing agent. Next, controlled amounts of hydrochloric acid are added to set an acid pH, so that ammonium is retained in the concentrate in the subsequent evaporation step. The last stage in the process is evaporation of the wastewater and drying of the product concentrate.

Because the hot stream of wastewater contains sufficient energy, evaporation is designed as a one-stage process. This stage consists of a vapor separator, a forced-circulation pump,

Figure 136. Block diagram of wastewater treatment in the Noell conversion process [323]

and a round-pipe heat exchanger. The evaporation temperature is chosen so that the flash steam obtained from the 205 °C wastewater provides the entire heat requirement for the evaporator. Because the concentrations and quantities are such that the wastewater would otherwise be too strongly concentrated, it is diluted by the return of a substream of distillate. A thin-film dryer heated with superheated steam (max. 240 °C) follows, in which the concentrate is dried to >90 % dry solids and packaged for landfill disposal. This mixed salt can be converted to technical-grade products, but the cost is high and this use is therefore not recommended.

The vapors from the second stage of the evaporation unit and thin-film dryer are condensed against water in surface condensers. All the vapor condensate is then pumped into its own tank, from which it is withdrawn for feedwater conditioning and preparation of chemicals.

Emissions and Products. *Synthesis Gas.* The content of $CO + H_2$ in the synthesis gas lies between 89 % for contaminated waste oil with a high heating value and 67.1 % for straw as a biofuel. Sewage sludges and residue fractions from residential waste fall in between.

Methane, the most stable hydrocarbon, is virtually absent. Higher hydrocarbons are only present in nano- or microgram traces. The concentration of nitrogen stems from the organic matter as well as the inert gas used in pneumatic conveying, especially in the case of residential waste fractions and straw. The nitrogen content can be significantly reduced if gas from the process is recycled.

Figure 137. Mass balance of the Noell conversion process

Sulfur entering with wastes is converted 90 % to hydrogen sulfide and 10 % to COS; the ratio does not depend on the type of fuel. Part of the

hydrogen sulfide is dissolved in the quench and scrub liquors, so that heavy metals not trapped in the granulate product are converted to insoluble heavy metal sulfides and precipitated. Ammonia and hydrogen cyanide are present at lower concentrations, and are removed from the gas and dissolved in the scrub liquor. They are eliminated in wastewater treatment. The clean gas has a heating value of 8 – 12 MJ/m^3 and can be used as a feedstock (synthesis gas) or fuel. After sulfur removal, the gas surpasses the standards of the 17th Federal Pollution Control Regulation.

Figures 137 and 138 show the mass and energy balances.

Figure 138. Energy balance of the Noell conversion process
IM = Inorganic material

Melt Granulate. Inorganic species inlet with the wastes are discharged from the gasifier as a melt and pelletized in the quench chamber. The granulate represents a sink for nonvolatile heavy metals. A small fraction is trapped in the granulated product. Most is precipitated in sulfide form and filtered out of the wastewater as solids. The process water solids are the sink for volatile heavy metals. A key point for economic utilization of the pellet product is its elution behavior. Elution values for pelletized melt product from residential waste, bituminous coal firing, and Freiberg gneiss (a native rock) are similar.

Solids from Wastewater. Solids from wastewater, consisting of process water solids and evaporator residue, must be discharged from the plant. According to the wastewater treatment flowsheet, process water solids in the form of filter cakes are obtained after flocculation and precipitation of heavy metals and before the partly treated water is forwarded to other operations.

In general, an overall technology that discharges no wastewater is needed. The excess water is evaporated by waste heat. The evaporation residue is a mixed salt, which is classified as nontoxic and can be disposed of in hazardous-waste landfills. The composition and balance of the solid residues are as follows:

Silicon	23 – 46 wt %
Aluminum	9 – 16 wt %
Calcium	13.5 – 39 wt %
Sodium	0.5 – 0.9 wt %
Magnesium	2.1 – 3.1 wt %
Potassium	0.4 – 1.6 wt %
Iron	6 – 19 wt %
Copper	0.01 – 0.12 wt %
Chromium	0.006 – 0.044 wt %
Nickel	40 – 180 mg/kg
Zinc	0.004 – 0.011 wt %
Lead	0 – 0.01 wt %
Cadmium	0 – 0.9 mg/kg
Mercury	0 – 0.6 mg/kg
Chlorine	0
Phosphorus	4 – 17.5 wt %
Sulfur	0 – 0.1 wt %
Carbon	0 – 0.3 wt %

The quantities of process water solids and evaporation residue, which are approximately equal, are governed by the concentrations inlet with wastes and residues. These levels of lead and zinc mean that the process water solids are a zinc – lead blende that can be processed by metallurgical methods.

Development of the Process. Entrained-bed gasification was developed independently and concurrently by Noell, Würzburg, and the Deutsche Brennstoffinstitut, Freiberg. Scaleup

began around the end of the 1970s and a full-scale experimental plant was operated from 1984 to 1988.

A 3 MW demonstration plant is available at Freiberg for fundamental research, especially with substances not covered by previous experience. This has been in operation since 1979. Some 60 substances have been gasified and their material and energy balances worked out.

An entrained-bed gasifier with a capacity of 130 MW, corresponding to about 30 t/h of feed, has been producing town gas on an industrial scale since 1988. The feed consists of condensate products from fixed-bed pressure gasification of lignite. This plant, along with the fixed-bed pressure gasifier, is now part of the waste recovery center of the Lausitzer Bergbau-Verwaltungsgesellschaft.

Pyrolysis was tested in a pilot facility at Salzgitter. This plant was operated for half a year in 1985. After renovation, it was on stream for two years starting in 1986, pyrolyzing 10 396 t of waste in 6151 hours.

After assessment of extensive tests with the full-scale pyrolysis system at Salzgitter, approval for continued operation was granted, and the start of disposal operation is set for late 1995.

10. Deposition

10.1. Deposition Aboveground

10.1.1. Introduction

In this section, the aboveground disposal of wastes is referred to as landfill disposal or landfill.

In Germany as in many other countries of the European Union, landfill disposal has been accorded a low priority in official waste-management concepts. In practice, however, the majority of wastes continue to be deposited in landfills. The term landfill disposal includes a broad spectrum of disposal qualities, from unmonitored "dumps" with no technical installations up to well-engineered, equipped, and monitored landfills. This section, however, discusses only landfills where pollution of the environment can be largely eliminated.

10.1.2. Classification of Landfills

In most countries, wastes are placed in special kinds of landfills according to their demonstrated or presumed environmental impacts. The classification schemes often have not been precisely defined. An exception is the German federal state of North Rhine-Westphalia (NRW), which in 1987 stated exact definitions of six classes of landfills [331]:

1) Landfill class 1: Soil disposal
2) Landfill class 2: Disposal of mineral products (e.g., demolition waste)
3) Landfill class 3: Disposal of municipal solid waste (MSW)
4) Landfill class 4: Disposal of commercial and industrial wastes
5) Landfill class 5: Disposal of hazardous wastes
6) Landfill class 6: Underground disposal of hazardous wastes

Along with the general information required for classifying wastes under this scheme, disposal was also made dependent on the contents of specific substances in the waste or in the leachate.

Since 1993, the assignment of wastes to disposal sites in the Federal Republic of Germany has been governed by the "Technical Directive on Municipal Solid Wastes" (TA Siedlungsabfall, with two landfill classes) [332] or, for hazardous wastes, TA Abfall [333] with one class. These two regulations also limit the concentrations of certain substances in waste and leachate. Although the classification system is largely the same as that cited above, there is a crucial difference: in the NRW system, solid wastes can always be assigned to a landfill class, but the constraints on the classes set up by the TA Siedlungsabfall and TA Abfall are so narrow that in many instances it is necessary to treat the wastes before they can satisfy the classification criteria. The purpose of these new regulations is to secure the pretreatment of wastes such that an environmentally neutral form of disposal is ensured. Exceptions are built into TA Siedlungsabfall in the form of dedicated disposal sites for wastes not complying in all respects with the landfill class requirements.

Insofar as classification systems do exist in the several countries, they correspond to one of the two systems just discussed (sometimes in modified form).

A special class of disposal site exists in Great Britain and Ireland: the "co-disposal" landfill. This type of site handles MSW as well as industrial and hazardous wastes all together. The basic concept of this type of landfill is to accept the last-named wastes only in such quantities that the emissions by the leachate path are no higher than those of an MSW landfill. Tests are performed to determine the levels of various contaminants that can be trapped or degraded in the MSW. The result provides a basis for establishing total and short-term limits (per week or month) on the amounts of each contaminant that can be deposited in the landfill as a function of the amount of MSW deposited there. The maximum acceptable quantities of industrial and hazardous wastes are then derived from these contaminant limits and the concentration of the substances in the wastes. Wastes should be deposited in such a way that the contaminants escaping from them can be safely taken up by the municipal solid wastes and either immobilized or degraded.

10.1.3. Landfill Siting

The EU countries have no exact quality criteria for the selection of landfill sites.

The most important criteria for siting in most countries are geological and hydrological constraints. For example, the soil should have a low permeability and a high potential for retaining contaminants. The groundwater at the planned landfill site should not be used in producing drinking water either currently or in the future. These requirements, also referred to as geological barriers in Germany (see Section 10.1.4), represent the key requirements for a disposal site.

In addition, a number of special criteria must be taken into account in landfill siting: natural conservation and landscape protection regions, bodies of water, inhabited areas, infrastructure, and so forth. Sites where there is a danger of earthquake or mining subsidence must also be eliminated as far as possible.

While the last-named criteria can be researched in existing documents, in Germany a detailed exploration of the geological barriers at potential sites is required. Once this exploration has been completed for the prospective sites, a comparison should be performed as to environmental and geographical compatibility, and the most suitable site is selected. Then, by means of detailed investigation of the selected site, it must be demonstrated that the first explorations of the geological barriers and analyses of soil stability are correct in all points or that the site actually surpasses the first findings.

In order that landfills can be constructed even in regions where the geological conditions are poor, TA Siedlungsabfall permits the use of technical measures to supplement (or, in some German states, to replace entirely) inadequate geological barriers.

10.1.4. Landfill Safety Analyses

Recurring problems with landfills and the resulting impacts on the environment have made it necessary to conduct thorough environmental safety analyses for landfills. One consequence of these stringent safety analyses in Germany is the multibarrier concept. In contrast to disposal sites in the past, where a bottom liner was virtually the only safeguard against environmental impacts of the landfill, the multibarrier concept requires the use of a number of independent emission barriers [334], [335]. The following kinds of barriers are contemplated:

Barrier 1 is the pretreatment of waste in order to immobilize contaminants, since the long-term mobility of waste constituents is one of the most important parameters relating to the hazard potential of a disposal site.

Barrier 2 is the geology and hydrology of a landfill site. Because of the extremely long service life of a landfill, it cannot be excluded that artificial barrier systems may partially or completely fail over time. If this happens, the geological and hydrological barrier must ensure that escaping contaminants migrate slowly and at low concentrations.

The landfill material with its forecast behavior represents barrier 3. The processes taking place in the body of a landfill must be largely describable and predictable. The stability of the

deposited material and the immobility of its constituents thus constitute barrier 3.

The landfill foundation seal or bottom liner with leachate collection system is designated as barrier 4. The purpose of this system is to prevent leachate, possibly heavily polluted, from escaping into the surroundings. The liner and drainage system must remain fully functional for as long a time as possible.

The top liner with pecipitation runoff constitutes barrier 5. This system must control the penetration of precipitation into the landfill material and thus reduce its effects on barriers 3 and 4. At the same time, the deposited waste must be protected against weathering for as long as possible.

Barrier 6 comprises the maintenance, monitoring, and repair of the barrier systems. In view of the long existence of a landfill and the limited service lives of the technical systems, this barrier takes on special importance. Monitoring makes it possible to keep track of the functionality of the barrier systems, while repairability means that functionality is drastically extended over time.

Only the future will tell, however, how effective and feasible such a multibarrier system will be.

10.1.5. Lining and Drainage Systems

Since about 1980, in response to the finding that many unlined landfills had caused serious groundwater contamination, it has been increasingly recognized that the bases of landfills must be as tightly sealed as possible.

At first, natural mineral foundations were used, but also clay and plastic liners. Although natural inorganic materials were found in laboratory tests to have the required low permeabilities, in many cases the materials turned out to have a markedly higher permeability in natural deposits.

Mineral liners consist mainly of clay and other fine components, compacted in such a way that the individual layers exhibit extremely low permeabilities ($k < 5 \times 10^{-10}$ m/s). This type of liner is similar in makeup and structure to natural unconsolidated material and thus shares its long-term stability, but substances such as concentrated acids and alkalies can attack the structure and thereby increase the permeability.

Figure 139. Examples of a composite bottom liner (A) and a top liner (B) [332]

The plastic material most commonly used for liners is high-density polyethylene (HDPE) film. This plastic liner material has the drawback that its long-term stability (>50 years) is unknown. In contrast to clay liners, plastic liners are almost absolutely watertight, provided that the welds between sections are tight. Some solvents, however, permeate relatively fast through plastic liners without damaging them.

In order to combine the advantages and offset the disadvantages, the TA Siedlungsabfall prescribes a composite seal system for use in Germany [332]. The composite is made up of a mineral component and a plastic liner (see Fig. 139 A). The two liners must be placed contiguous to one another.

A liner system alone cannot, however, safeguard the soil against environmental impacts, because the leachate retained at the base of the landfill would escape through even the smallest flaws. Therefore, leachate reaching the liner must be removed as promptly as possible. Experience has shown that effective drainage is possible only with a fairly permeable gravel layer (ca. 0.3 – 0.5 m thick) with supplementary drainage pipes (see Fig. 139). It has proved necessary to use extra-coarse material (grain size 16 – 32 mm) for the drainage layer, since the leachate generated from many wastes contains substances that could precipitate outside the waste fill (e.g., in the drainage layer). When municipal solid wastes are disposed of, it is often required that they be biologically pretreated before or at the beginning of deposition so that reactions in the waste fill will not liberate acids that would dissolve and transport such products. The risk of encrustation decreases with increasing volume of the drainage layer and with increasing pore size. At present there is no method for removing encrusted material from the drainage layer. Because such deposits also threaten the drainage pipes, the pipes are regularly inspected with video cameras, then flushed with a high-pressure (8 MPa) water jet if necessary. Annual inspection and flushing has proved quite beneficial in terms of the functioning of the drainage system. These practices have restricted the length of drain pipes to ca. 300 m. Because any structural foundation (e.g., shafts) placed on the foundation liner must be regarded critically, the maximum pipe length has often dictated the maximum size of the landfill. To avoid this restriction, landfill designs in Germany increasingly use galleries on the landfill base, with leachate pipes (and sometimes also gas collection pipes) running into the galleries. The pipes must be designed so that the drainage pipes can be inspected and flushed at any time without admitting air from the outside. In MSW landfills, because of landfill gas diffusing into these galleries (see Section 10.1.6.5), special explosion protection measures are required.

Even when the pipes end in shafts outside the landfill, care must be taken not to admit ambient air into the pipes and the drainage layer, because air often promotes the precipitation of inorganic compounds from the leachate and biogenic deposits. At the same time, inspection and maintenance must be possible at all times.

To prevent the formation of leachate from landfills over the long term, TA Abfall and TA Siedlungsabfall mandate a "final cover" after closure of the landfill. Figure 139 illustrates such a cover. An equalizer layer must be located underneath the top liner proper to allow the collection of any gas that forms. Above the liner is a layer of soil in which vegetation can grow; this layer must be carefully drained so that precipitation water does not accumulate on top of the liner. Observation has shown that the quantity of leachate is drastically cut by the final cover, but it is not possible to say now whether complete avoidance of leachate is possible. A final cover can perform its intended function only if it is monitored and maintained over a long period (centuries or millennia).

10.1.6. Leachate and Gas Formation in Landfills

10.1.6.1. Processes in the Landfill

A variety of processes take place in all landfills, depending on the type of wastes. These processes are biological, chemical, and physical in nature, or a combination of any or all of these. In only a few types of landfill, such as those for demolition waste and soil disposal, can it be assumed that these processes will be of about the same order of magnitude as processes in natural rock and soil and thus of secondary importance. The leachate formed by precipitation dissolves substances from the wastes and also influences the various processes, generally accelerating them. The processes occurring in landfills are extremely complex and cannot be described in detail.

Some examples of individual processes that can occur in a landfill, depending on the nature of the wastes as well as the ambient conditions in the waste fill, are the following [336]:

1) Precipitation of metals as hydroxides, oxides, carbonates, sulfides, silicates, humates, etc.
2) Mobilization of metals by formation of complexes
3) Mobilization of metals as a result of the lower pH in the acetic phase (see below) or when the wastes contain acidic inorganic substances
4) Changes in solubility behavior due to aging

Except in dedicated landfills with wastes of simple composition, there is always a very complicated interaction of these processes, which ultimately determine the nature of the emissions.

The complexity of the processes becomes much greater if the wastes have organic constituents. Dissolved organic substances take part in some of the processes, and all organic materials (plastics being among the few exceptions) are subject to biological reactions, which vary in type and intensity.

These biological processes have been extensively studied in MSW landfills [337–343]. Immediately after deposition and at the outer surface of the landfill (to a depth of ca. 1 – 1.5 m), aerobic reactions take place. The microorganisms involved require oxygen to degrade organic matter, generating CO_2, H_2O, biomass, and heat as end products. Generally, wastes are exposed to atmospheric oxygen for only a relatively short time, and this means that only the readily degradable substances react. As soon as the oxygen supply ends, anaerobic conditions come into being; these lead to methane fermentation, which continues for a long period (methanogenic phase). During this time, organic substances are converted to CH_4 and CO_2 as well as small amounts of biomass and energy. This anaerobic process proceeds in three phases that can be relatively exactly distinguished. For the reaction mentioned above, these phases must be in equilibrium. The three steps in the anaerobic process are as follows:

1) Hydrolysis: facultative bacteria convert the organic substrate (proteins, fats, carbohydrates, etc.) into simple organic substances such as amino acids, glucose, etc.
2) Acetic phase: the end products of hydrolysis are converted by anaerobic bacteria to volatile fatty acids, CO_2, and H_2.
3) Methanogenic phase: acetogenic bacteria convert volatile fatty acids to acetic acid, CO_2, and H_2; methanogens immediately convert these end products to CH_4 and CO_2. Both groups of bacteria are extremely sensitive, strictly anaerobic, and substrate-specific.

All three phases are collected under the term methanogenic phase. In industrial application this process is held at equilibrium by means of the operating conditions and monitoring. Because such measurement and control are not possible in a landfill, equilibrium is not attained, at least in the first phase of waste deposition. As a result, the end products of hydrolysis and acetic fermentation, which are formed quickly, are transported away with leachate through the fill; in this way they either alter the milieu for processes taking place elsewhere or they become contaminants in the leachate reaching the leachate collection system. Equilibrium is established only when the slow-growing methanogenic bacteria develop, mediating the reaction to the gases CH_4 and CO_2 and thus reducing the organic contamination of the leachate. With increasing contents of readily degradable organic matter in the waste, the hydrolysis and acetic fermentation processes become faster and the equilibrium of complete methanogenic fermentation is further delayed. Although methanogenic bacteria in industrial processes with liquid media are observed to be highly sensitive, the same bacteria exposed to the solid medium of the waste are not so sensitive. High methane production rates are often observed under conditions that would seem to rule them out.

Because the content of organic matter in the waste is not unlimited, in the long term the above processes must cease. With neither CO_2 nor CH_4 being produced in significant amounts, air and thus oxygen can now diffuse into the waste fill, re-establishing aerobic conditions. This is not expected to occur in MSW landfills for centuries or millennia. If the ambient conditions change in this way, changes in leachate contamination and possibly increases in the concentrations of some constituents cannot be ruled out.

10.1.6.2. Water Balance

Because of the heterogeneous nature of the material and the granular structure, the behavior of water in a landfill is much more complex than in a natural soil body. This is especially true of landfills for municipal solid wastes. The coarse waste structure prevents uniform saturation of the fill, so that broad leachate flow paths can form. In addition, materials such as plastic film create barrier layers, paper stores water, and organic matter can absorb and distribute water as well as hinder its flow. Figure 140 illustrates the water balance. With regard to the total quantity of leachate, it is important how impermeable the waste surface is and how much precipitation can reach it. In many landfills, the quantity of leachate is reduced over a long time by water storage in the waste.

Figure 140. Schematic water balance of an MSW landfill

Leachate quantities observed at many landfills in the past (Fig. 141) were 10 – 25 % of precipitation [337], [339–341]. In very young landfills with high storage capacity, in contrast, leachate was less than 10 % of precipitation; in old landfills, after exhaustion of the storage capacity, it was as much as 40 % of precipitation. The figures given are yearly averages because the leachate discharge varies widely over the year. Figure 142 shows the leachate discharge of a landfill, with high values at the end of winter and spring and low discharges in late summer and autumn.

The storage capacity of waste has been significantly cut, above all through the separation of paper and the separate disposal of demolition waste and soil. Leachate rates of 30 –40 % of precipitation are often seen today as a result. At some landfills for MSW, the organic wastes are also separated for composting. The poor compactability of the remaining wastes together with their low storage capacity means that the leachate flow increases to 60 – 80 % of precipitation, with a particularly irregular discharge pattern [344].

At non-MSW landfills, the quantity of leachate is so strongly dependent on the type of waste and its compaction that rates from ca. 0 % to ca. 100 % of precipitation are possible. For example, industrial and hazardous waste landfills in the Federal Republic of Germany have recorded leachate discharges ranging from 10^{-5} to $1.86\,m^3\,m^{-2}\,a^{-1}$ [336].

10.1.6.3. Leachate Quality

Leachate quality is strongly dependent on the nature of the wastes and on the processes taking place in the fill (see Section 10.1.6.1). The measured values, of course, apply only to the initial period of a landfill, since there is not yet any experience with the disposal of wastes from our industrial society over hundreds or thousands of years. Because the substances placed in landfills and mobilized are not infinite, the emission stream must stop some time. It is difficult, however, to estimate when this will happen.

Table 31 lists the concentration ranges in leachates from several types of landfills in the EU [337], [340], [341], [344–350]. The landfill types in the table are not identical to those listed in Section 10.1.2, because the study concerned existing landfills (older than 3 – 5 years) and not new ones that come under the classfication scheme. As was mentioned in Section 10.1.6.3, MSW landfills often experience an acetic phase in which organic contaminant levels are high, which is later followed by a methanogenic phase in which organic contaminant levels are moderate. This progression can be seen in Figure 143, which presents data for an operated landfill.

Figure 141. Precipitation and leachate quantities for various landfills

Figure 142. Precipitation and leachate flow for a company landfill

Figure 143. Concentration of various leachate components as a function of time

Figure 144. Variation in COD for a landfill with low water storage capacity of the waste

Because the organic contamination is due to volatile (lower) fatty acids, the pH falls and the concentrations of some inorganic substances such as calcium and iron rise markedly. Sulfate also undergoes changes due to biological processes, and these are energetically more favorable than methanogenic fermentation, so sulfate is largely reduced before full methane production is achieved. Care in the handling of problem substances (heavy metals, organic pollutants) has led to appreciable reductions in contamination of leachates with these substances. If smaller storage capacities result in very uneven discharges, large fluctuations in leachate contamination often accompany this effect, as shown in Figure 144 [344].

Operating techniques such as the placement of wastes in thin layers (depth 0.15 – 0.5 m) and recirculation of leachate have made it possible to reduce significantly the high organic contamination levels during acetic fermentation (Figure 145) [338], [341]. These measures prolong the initial aerobic phase and improve the water distribution.

Estimates indicate that water-polluting species such as nitrogen and organics (COD, BOD_5) present in leachate from many older landfills may necessitate treatment for 200 – 600 years [342], [343]. This time period may be much longer in the case of volatile organohalogen compounds (AOX), so that a reduction of the amount of these substances in wastes is urgently needed.

10.1.6.4. Leachate Treatment

Contaminants in leachates from landfills accepting MSW and some other, more highly contaminated wastes mean that these leachates cannot be released directly into surface waters. In Germany, the constituents relevant to treatment are organic matter (COD, BOD_5), ammonium, and AOX [351]. Often 400 – 1500 mg COD/L is not biodegradable and must be removed by physicochemical methods. The following combinations of processes are therefore employed:

1) Biological treatment to eliminate BOD_5 and nitrification and denitrification to remove nitrogen; flocculation if necessary to remove high molecular mass COD and AOX; adsorption on activated carbon to eliminate COD and AOX (with thermal regeneration of the activated carbon).
2) Biological treatment to eliminate BOD_5 and nitrification – denitrification to remove nitrogen; oxidation of COD and AOX with ozone (and UV radiation if appropriate); final biological treatment if necessary to remove biodegradable oxidation products.

Figure 145. Typical COD and BOD_5 curves for operated landfills with different operational methods a) Deposition in 1.5 – 2 m layers; b) Deposition in thin layers; c) As (a) but with leachate recirculation

Figure 146. Variation of gas production with time for total gas quantity $G_e = 0.06 - 0.18\,m^3$ (STP)/kg and half-life $t_{0.5}$ of 3 and 10 years

3) Biological treatment if necessary to eliminate BOD_5 and nitrification – denitrification to remove nitrogen; stripping of ammonium if there is no biological pretreatment; one to three stages of reverse osmosis (depending on contaminant levels and required effluent values) to separate and concentrate nearly all substances contained in water; evaporation and drying of the concentrate and, if necessary, of ammonium sulfate liquor from stripping.

The third variant removes virtually all contaminants from the leachate but involves much technical effort and financial expenditure. The residues are readily soluble and therefore have to be stored underground to protect them from

weathering. In the first two processes the only residues are those from biological treatment and flocculation, if practiced; these present few disposal problems. While these processes offer lower costs than the chain of operations involving reverse osmosis, costs of leachate processing are still substantial.

Figure 147. Variation of gas production with time for a landfill in which 100 000 t of waste were deposited over the course of 20 years

10.1.6.5. Gas Formation

The formation of gases in landfills can take place in several ways:

1) Evolution of volatile waste constituents (especially solvents)
2) Reactions between waste species resulting in gas production
3) Anaerobic conversion of organic substances by methanogenic fermentation (see Section 10.1.6.1)

Although it is known that the first two processes do take place in some industrial and hazardous waste landfills, little is known about them. Gas production by methanogenic fermentation is much more familiar because it occurs in all MSW landfills [337], [352–354]. Gas production begins spontaneously, some 0.5 – 3 years after deposition of the waste, and quickly reaches a maximum value from which it then declines slowly over a period of decades (Fig. 146). This gas production is fairly rigorously described by the decay function of Figure 147. The maximum quantity of gas produced is ca. 0.06 – 0.18 m^3/kg of waste (gas volume measured at STP). If the fraction of organic matter in the waste is lower, the total quantity of gas producible (G_e) decreases, and the half-life generally becomes longer. By way of example, Figure 147 shows the hourly gas output of a landfill in which 100 000 t of MSW per year was deposited over a 20-year span. The gas from MSW landfills consists of ca. 55 % CH_4 and ca. 45 % CO_2. Because the waste fill is not a closed system, air is often included in the measured gas flow; the above values then decrease. Less than 1 % of the gas consists of a wide range of trace substances, which (among other effects) render the gas odorous. Their concentrations in mg/m^3 are as follows [355]:

Ethane	0.8 – 48
Ethylene	0.7 – 31
Propane	1.4 – 13
Propene	0.04 – 10
Butane	0.3 – 23
Butene	1 – 21
Pentane	0 – 12
2-Methylpentane	0.02 – 1.5
3-Methylpentane	0.02 – 1.5
Hexane	3 – 18
Cyclohexane	0.03 – 11
2-Methylhexane	0.04 – 16
3-Methylhexane	0.04 – 13
Cyclohexene	2 – 6
Heptane	3 – 8
2-Methylheptane	0.05 – 2.5
3-Methylheptane	0.05 – 2.5
Octane	0.05 – 75
Nonane	0.05 – 400
Cumene	0 – 32
Bicyclo[3.2.1]octane-2,3-methyl, 4-methylene	15 – 350
Decane	0.2 – 137
Bicyclo[3.2.0]hexane-2,2-methyl, 5-methylethyl	12 – 153
Undecane	7 – 48
Dodecane	2 – 4
Tridecane	0.2 – 1
Benzene	0.03 – 7
Ethylbenzene	0.5 – 236
1,3,5-Methylbenzene	10 – 25
Toluene	0.2 – 615
m/p-Xylene	0 – 376
o-Xylene	0.2 – 7
Trichlorofluormethane	1 – 84
Dichlorofluormethane	4 – 119
Chlorotrifluormethane	0 – 10
Dichloromethane	0 – 6
Trichloromethane	0 – 2
Tetrachloromethane	0 – 0.6
Chloroethylene	0 – 264
Dichloroethylene	0 – 294
Trichloroethylene	0 – 182
Tetrachloroethylene	0.1 – 142
Chlorobenzene	0 – 0.2

Volatile chlorinated hydrocarbons are transported by the landfill gas.

The gas produced diffuses out of the landfill and can cause suffocation of plants, fires, and – in certain mixtures with air – explosions. The collection and disposal of this gas is therefore essential.

10.1.6.6. Landfill Gas Recovery

To avoid hazards in the operation of the landfill and for the surroundings, the gas produced must be extracted from the landfill. This is performed with collection pipes placed in the waste fill and surrounded by gravel. The pipes can be either vertical or horizontal. They must be carefully sealed in the outer parts of the landfill so that no air can enter the system. Mixing with air can lead to explosions. The gas is drawn from the collection pipes by suction (1 – 3 kPa) generated by a fan.

Because maximum gas production occurs as little as 0.5 – 3 years after placement of the waste, gas extraction during landfill operation is often necessary. This can be done more effectively and with less disruption if the gas recovery system is horizontal. It is still a matter of doubt, however, whether such systems will remain functional in the long term. Additional wells for vertical gas recovery systems are often constructed after the closure of a landfill.

The extracted gas is saturated with water because of the ambient conditions in the landfill. As soon as the gas cools after leaving the waste fill, water condenses from it. The water is frequently contaminated with high levels of volatile chlorinated hydrocarbons, so it must be separated and disposed of. Only when the contaminant levels in this condensate are the same as in the leachate can the two water streams be treated together.

The gas is destroyed in flare systems designed for high-temperature combustion; otherwise, the presence of chlorine in the compounds would pose the danger of dioxin and furan formation.

Landfill gas has an energy content of ca. 4 – 5 kWh/m^3 (not including conversion losses), and so using it for energy production may be feasible if the quantity is large. Some options are:

1) Direct combustion to generate heat
2) Combustion in motors or turbines to generate electricity
3) Removal of CO_2 and trace substances to obtain methane

The only forms of utilization that have been practiced on a significant scale are direct combustion with heat recovery and combustion in motors to generate electricity. Given typical landfill sizes, electrical capacities of 0.5 – 2 MW can be installed.

In the case of old landfills with low gas production rates, biological oxidation of methane in compost or soil filters is a possibility.

10.1.7. Landfill Operation

In the receiving portion of a landfill, arriving waste is commonly weighed and visually examined or inspected to determine its identity. The waste is then unloaded from the delivery vehicle in the operations section. A further visual identity check should be performed here. Next, the waste is incorporated in the fill one lift at a time. Inorganic wastes are often bulldozed into the fill. The height of the lifts often depends on the nature of the waste. Municipal solid wastes are compacted by heavy, steel-tired loaders (compactors). The wheels of these loaders have steel teeth welded on; the tips of the tooth generate a high peak pressure as the vehicle moves over the fill, compacting the MSW. In the past, such wastes were often placed in 1.5 – 2 m lifts and then compacted. It has been found that the pressure exerted by compactors is not enough to optimally compact this high a lift. Today, lift heights at many landfills are 0.15 – 0.5 m.

Landfill operators are responsible for protecting the environment from dust and odors. High-growing vegetation is often planted around the landfill boundaries as a visual shield.

10.2. Underground Deposition

10.2.1. Introduction

Progress in underground construction in recent decades means that the building of underground cavities today is economical, safe, and competitive with aboveground structures in many

Table 31. Concentration ranges in leachates from various types of landfill

Parameter	Demolition waste landfills	Monolandfills (for incinerator residues)	Industrial waste landfills	MSW landfills	MSW landfills	Co-disposal landfills	Hazardous waste landfills

∗ Newer landfills with separation of refuse.

respects. Furthermore, the use of underground cavities offers certain advantages over surface facilities, particularly with respect to maintenance, operation, and safety. Underground storage for petroleum products and gaseous hydrocarbons has proved incomparably cheaper than freestanding storage.

Underground waste deposition has become increasingly important in the waste management field. The reasons lie partly in the decline of mining. Strong international competition in the extraction of raw materials has led to a search for new, less costly sources. In Germany, some mining companies have begun offering to dispose of wastes in their deep or surface mines in parallel with their mineral extraction programs. In addition, stiffening competition on the international raw-materials market has forced the closure of many German mines. As a result, much underground capacity suitable for waste storage and disposal has become available. In a few instances, underground cavities have been constructed specially for waste disposal; this is particularly so in the field of ultimate disposal of radioactive wastes. Underground waste disposal and recycling has grown into a new economic sector in recent years, and development in the field is rapid, driven by changes in the waste and residue market, the oversupply of unused surface and deep mines, and also by changing conditions of ownership. There is a huge stock of exploitable tailings and spoil piles as well. The market can be expected to change because the legal situation is not clear at the moment.

The main aspects of underground deposition in Germany are covered by TA Abfall and var-

ious waste management and mining laws. The government ministries with jurisdiction in this area, as well as the regulatory authorities dealing with mining and waste, are now concentrating their efforts on closing the gaps that still exist in the laws and implementing regulations. The creation of the European single market, however, suggests that more changes are in store for this sector.

10.2.2. Types of Mines and Their Relevance to Waste Deposition and Recycling

Essentially there are three ways of depositing wastes in mines:

1) The use of existing cavities created by mining raw materials
2) Construction of new mines specifically for waste disposal in suitable geological formations
3) Injection of liquid residues and wastes into natural cavities, such as pores and joints in subterranean formations (e.g., exhausted gas and oil fields)

Three forms of mining are practiced: surface (open-pit, open-cast, strip) mining; underground (deep) mining; and borehole mining.

In surface mining, deposits lying under shallow cover near the surface are worked where the overburden can be economically removed with existing technology. In Germany, lignite, rock, and earths are mined in this way. As a rule, surface mines are carried to depths of 100 – 200 m. Deeper pits, such as the lignite mines in the Aachen district, extend to depths of 400 – 500 m. In the past, surface mines were often used for waste disposal. Germany has countless worked-out pits and quarries where clay, sand, gravel, and stone were produced, as well as closed lignite mines, and in the past these were used – sometimes casually – as dumps. Today, because of the lack of foundation seals and other defects in water-retention and drainage practices, some of these dumps have become major hazardous waste sites that will require major efforts to clean up.

Most surface-mine sites are used for the disposal of mining wastes and the replacement of overburden. Certain residues, such as ash, slag, and gypsum derived from flue-gas desulfurization at lignite-fired plants, can be included with this material with no detrimental impact on groundwater. Lignite ash has a buffering action on the sometimes very acidic deep groundwater and may actually have a beneficial effect on the groundwater situation. Surface mines where clay was extracted (e.g., clay pits and brickyards) used to be employed as hazardous waste landfills. Because the dense clay formations were mostly removed in the mining operation, these cavities often lack an adequate foundation seal, so that isolation from deeper geological formations can no longer be guaranteed. Gravel and sand deposits commonly occur in highly permeable groundwater horizons near the surface and are unsuitable for the deposition of any kind of wastes except completely inert materials. Stone quarries are generally unsuitable for waste disposal too, because of the jointed character of the rock. If they are used for this purpose, technical modifications such as liners at the base and sides must be employed to provide the necessary impermeable barrier between the waste and the geological surroundings.

In subsurface mining, raw materials are won by driving cavities into the geological formation, and the overburden is left in place. Deep mines require accesses for transportation, ventilation, and drainage. These accesses take the form of galleries or shafts, which may be inclined or vertical, depending on the form of the deposit. In Germany, coal, potassium compounds, rock salt, and ores are extracted by deep mining.

Borehole mining is a special form of mining, mainly used for petroleum and natural gas production. This technique is best suited to liquid and gaseous raw materials, which may lie at great depths. The variant of solution mining is used for salt deposits. The cavity left behind by this type of mining is often utilized for gas and petroleum storage.

The use of mine cavities for the deposition of residues or wastes is governed by one of three laws, depending on the nature of the material: the Mining Act (Bundesberggesetz), the Waste Act (Abfallgesetz), or (for radioactive wastes) the Atomic Act (Atomgesetz).

When wastes generated in the prospecting, production, beneficiation, and refining of raw materials and subject to inspection by the mining authorities are to be replaced in mine cavi-

ties, they fall under the German Federal Mining Act (Bundesberggesetz) [356] and must be covered by an approved operating plan. Mineral residues not derived from mining can also be used in stowing.

If wastes and hazardous wastes are to be disposed of, all facilities, mines, caverns, and surface workings are subject to mandatory approval under applicable eminent domain provisions of waste-management law [357]. The deposition of radioactive wastes in mines, caverns, or boreholes is regulated under the Atomgesetz [358]. Facilities used for this purpose are again subject to approval; they simultaneously fall under supervision by the mining authorities and require the submission of a mining operations plan for supplemental approval. A regulation called Technical Directive on the Disposal of Hazardous Waste (TA Sonderabfall) [359] has been issued to cover the deposition of wastes in mines; it sets forth requirements on the quality of the underground facilities as well as their surroundings, the disposal method, the waste spectrum, and other points. An interstate working group on mining in Germany also published an engineering code relating to the disposal and reclamation of mineral raw materials and wastes used as underground stowage [360].

10.2.3. Safety Requirements for Operation and Closure of an Underground Deposition Site or a Mine Subject to Stowage

Mine cavities used for the disposal of wastes or the storage of residues are classified in five categories; the principal parameters are the form of the deposit, the groundwater situation, and the mining method. TA Abfall deals with the Type 1 underground deposition site, the salt mine. Here the barrier between waste and surroundings is the salt formation. If the salt is not very thick, additional layers in the overburden are required for sealing against groundwater. Such a working is sealed by lining the shaft where it passes through the groundwater horizon. The waste deposition rooms are sealed by closure systems such as embankment dams and also by the shaft closure required after the operational phase. As far as the technical parameters of the cavities during operation are concerned, stability must be ensured. The wastes themselves must not react with one another or with the host rock, so that no gas evolution or dissolution of the salt can occur. Underground deposition sites of this type are already in service or planned in the German states of Baden-Württemberg, Hesse, North Rhine-Westphalia, Lower Saxony, Saxony-Anhalt, and Thuringia.

A variant of Type 1, salt mine, is underground deposition site Type 2, the salt cavern. This cavity is likewise isolated from its surroundings by impermeable salt formations that guarantee safe containment of the wastes. In contrast to Type 1, this structure is created by solution mining. Access to the surface is through a borehole. Accordingly, the wastes must be placed in the salt cavern through a borehole; they can be delivered by free fall, pumped, or pneumatically conveyed. Unlike the wastes for Type 1 underground deposition, which can be either packaged wastes or unpackaged stowage materials in the form of slurries or the like, wastes for Type 2 deposition are not in containers. Because of intensive salt mining in Germany, large volumes are available for waste deposition and there are opportunities for the stowage of residues; this is expected to grow into a self-sustaining disposal market in coming years. Like Type 1, Type 2 is also covered in TA Abfall.

Underground deposition facilities of Types 3, 4, and 5 are not dealt with in TA Abfall [361].

Type 3 deposition involves mines in non-aquifer formations. Such a mine is driven in a geological formation that may be permeable but does not have any groundwater flow either because of impermeable roof rocks or as a result of special tectonic conditions. The underground cavity is sealed off from the aquifer by a tight layer; access is via a shaft, which must be sealed with a shaft plug after the end of the operational phase. The rooms in which wastes are deposited can also be closed off by embankments. As in the salt mine, a stability analysis must be performed during the operational phase, and on-site personnel must be in charge of ventilation and must inspect the residues and wastes from an occupational-health standpoint. Wastes can be deposited in containers, pumped in through pipes, or conveyed by pneumatic systems or belts. As in the case of the salt formations, wastes must not evolve gas. Mines of this type, chiefly in ore-producing regions, are being prepared for underground deposition service.

Type 4 underground deposition facilities are mines in aquifers. During the operational phase, the mine rooms are kept dry by drainage systems. After these systems are shut off, the wastes and residues are located in the groundwater. Mines of this type are used for stowage chiefly in coal-mining regions. Care should be taken that the elution behavior of the materials – which arrive at the disposal site chiefly as concentrated and dilute slurries and are stabilized on-site by the addition of pozzolanic cements – is such as to prevent appreciable releases of contaminants.

The Type 5 category of underground deposition sites is made up of mines above the aquifer, which generally are dry. Under some circumstances, however, precipitation water must be expected to penetrate into the roof rocks or the mine itself, so that permanent isolation of the wastes from the groundwater cannot be guaranteed. In mines of this type, wastes are deposited by on-site personnel; as in the Type 4 case, care should be taken that the wastes, usually consolidated with pozzolanic cements, are immobilized so that contaminants will not be eluted into the groundwater.

A special form of waste disposal is injection into natural pore or joint volume. The petroleum and natural gas industry commonly uses exhausted oil and gas fields for the storage of formation water produced along with the oil and gas. At some German sites, however, waters not originating in field operation – mainly saline waters from salt refining – are injected into deeper-lying joints and pores. As a rule, the geological formations are isolated from exploitable groundwater by impermeable roof rocks.

When constructing underground deposition sites, care should be taken that contamination of the atmosphere and hydrosphere and detrimental changes in the surroundings of the site are avoided. This essentially means testing the geology and hydrogeology of the site and of the underground space considered as a barrier system. Engineered safety systems must be used to secure accesses with suitable closure systems. The regulatory approval procedure calls for a safety analysis based on safety testing of the entire system, together with accident analyses. In addition, the wastes to be disposed of must be rendered compatible in the sense of disposability and possible chemical reactions with the barrier systems and the enclosing rocks.

10.2.4. Wastes and Residues for Deposition in Mined Cavities

Wastes deposited in underground cavities must be brought into a form suitable from the standpoint of geotechnology, occupational safety and health, and transportation. One way of achieving this is to package the wastes in containers; another is to subject them to physicochemical or, more often, thermal treatment.

The spectrum of wastes suitable for underground deposition essentially takes in two major waste categories:

1) Wastes of mineral origin and those stemming from refining processes; examples are metallurgical slags, ashes, slags and dusts, mineral sludges, and nonferrous metal wastes
2) Wastes from conversion and synthesis processes; examples are salts, oxides and hydroxides, pesticide wastes, pharmaceutical manufacturing wastes, petroleum-based greases and waxes, coating materials, and catalysts

Not suitable for underground disposal in accessible cavities are wastes that have a penetrating odor, give off-gas, or form fine dusts that can be carried by ventilation air and present a hazard to the mine personnel. Wastes that ignite spontaneously or sustain combustion, explosive wastes, and wastes that form toxic or explosive gas – air mixtures under the conditions prevailing in the mine rooms are also excluded. This means that wastes whose organic character makes them liable to decompose and endanger the health of the mine personnel are essentially not eligible for this kind of disposal. The spectrum of stowable materials and residues includes wastes from coal-fired plants, slags and ashes from thermal treatment of wastes, residues and wastes from foundries, construction wastes, wastes from reaction and synthesis processes, and abrasive residues. Before wastes can be deposited or residues recycled, a substantiated description of what is planned must be submitted by way of an assessment. This declaration must take the form of disposal and recycling certificates in the case of residues and wastes subject to regulatory supervision. For other residues and wastes, the requirement of a disposal certificate

holds as appropriate. The monitoring of reclamation practices includes inspection of manifests on delivery, a comparison of the delivery manifest with the recycling certificate, a determination of the quantity, and an identity check. Pursuant to mining law, the authority is responsible for monitoring the disposal procedures in cooperation with other regulatory bodies.

10.2.5. Examples of Spaces Used for Waste Deposition and Spaces Packed with Residues Not Generated in Mining

Hazardous wastes have been placed in the Herfa-Neurode underground depository of Kali and Salz since 1972. The plant has been designated an underground waste deposition site and licensed under waste management law. This facility is part of a mining territory of the Wintershall natural potassium salt mine, which is still producing the salt. As parts of the pillar-and-stall working are closed, rooms are bulkheaded off and used for the deposition of hazardous wastes. Since mining continues in the complex, wastes must be packaged in containers. The prerequisite for disposal use is the possibility of isolating the closed and decommissioned mining territory from the producing territory. Cavities made by mineral mining must be stable. The mine in which the wastes are deposited must be dry and absolutely water-free. The geological conditions comprise a Zechstein salt formation ca. 300 m thick with horizontal bedding overlain by a 300 – 600 m thick roof. Further impermeable horizons in the form of clay beds some 100 m thick are found in the overlying rock; these seal the mine off from higher formations and groundwater.

Before the deposition of wastes, the closed cavities are upgraded by safety measures such as roof anchoring, removal of loose material, and treatment of the floor for vehicle access. The underground disposal site was approved for this service by the Hessian mining authorities in accordance with waste management law. The construction and operation are governed by regulations implementing the Abfallgesetz as well as provisions of mining law. The Hessian Bergamt (mining inspectorate) is the supervisory agency for the underground disposal site; this body includes other authorities and institutions in its approval procedure, such as Hessische Industriemüll GmbH, the Hessian Bundesanstalt für Umwelt, and the Hessian environmental ministry.

On delivery, wastes are classified by substance class and placed in the appropriate areas. In all, 16 substance classes are stored in separate rooms; the major classes are water-hardness salt residues, electrolytic cell muds, chemical residues, drying agents, and residues from flue-gas cleaning systems at hazardous waste and domestic waste incineration plants.

The wastes are generally packaged. It is also required that the wastes be neither explosive nor spontaneously combustible. They must be solid, must not contain any free liquid, and must not evolve gases. Radioactive wastes are excluded. Wastes are inspected and sampled before deposition.

The second underground waste disposal site in Germany is the Heilbronn salt mine of Südwestdeutsche Salz, which received approval in 1986 for the disposal of residues from flue-gas cleaning units at domestic and hazardous waste incineration plants. Up to mid-1994, a total of 200 000 t of flue-gas cleaning residues had been deposited in the site. The mine was built to extract salt from a Middle Muschelkalk salt formation ca. 40 m thick; it lies at a depth of ca. 170 – 210 m. Wastes are packaged in either sheet-metal containers or big bags and laid one on top of another in several lifts until the rooms are completely filled. After each room was filled with ca. 15 000 t of flue-gas residues, access was closed off with a wall and in this way the room was isolated from the ventilation system.

Germany's third underground disposal site, the Zielitz mine of Kali und Salz, is located in Saxony-Anhalt State. As at Herfa-Neurode, potassium salt is mined in board-and-stall fashion in a horizontally bedded formation. Closed and mined-out rooms are used for waste disposal. After individual rooms are filled, they are sealed off from the ventilation system with walls. The facility, licensed under waste management law, will begin disposal operations in 1995.

Two other sites are preparing for the regulatory approval process for hazardous waste disposal. These are the Riedel mine of Kali und Salz in Lower Saxony and the Borth mine of Solvay in North Rhine-Westphalia. The Borth mine is a pillar-and-stall working in horizontally bedded

Zechstein salt formations; the Riedel mine is in a salt stock where both mineral salt and native potassium salts are extracted by shrinkage stoping.

In addition to waste disposal in mines approved for this purpose, residues are increasingly being used in stowage. When deposits in mines have been driven through and mined out, mining law requires that they be rendered safe. In many such locations, long-term stability and freedom from damage at the surface cannot be guaranteed, so the mining authorities have decreed that they must be packed. To lower the costs of the mine operators, the mining authorities are increasingly allowing materials not originating in the mining operations to be used in stowage; the mine operator commonly realizes some income by accepting such "foreign" material.

One of the oldest packed mines where foreign fly ash from coal-fired power plants was used in stowing is the Wohlverwahrt-Nammen mind of Barbara Rohstoffbetriebe in North Rhine-Westphalia. This iron ore mine, worked by the pillar-and-stall method, continues to produce ore. For many years, power-plant fly ash, which has pozzolanic qualities, has been incorporated in the stowage to ensure the long-term stability of mined-out rooms until the mine is finally closed.

The Bernburg mine of Mitteldeutsche Salzwerke GmbH in Saxony-Anhalt state, also a pillar-and-stall salt mine, has accepted foreign stowage material for years in order to stabilize its salt pillars in some areas.

A pilot stowing program is undergoing tests in the Kochendorf salt mine of Südwestdeutsche Salzwerke. A similar pilot project is in operation at the Bleicherode mine of the Gesellschaft zur Verwertung und Verwahrung von Bergwerkseigentum (GVV) in Thuringia.

In the coal-mining sector, a pilot study aimed at reducing surface damage is being carried out at the Zollverein mine, where the caving method was employed. Foreign residues are being successfully used in stowing. Stowing of caved rooms with foreign material is also being practiced at the Haus Aden/Monopol mine at Bergkamen, Hugo Consolidation at Gelsenkirchen, and Walsum at Duisburg.

The closing of other mines is expected to generate a new market in stowage technology; it is anticipated that the method will gain approval under both mining and waste management law.

Now in use for the disposal of radioactive wastes is the Morsleben salt mine, which was licensed under the nuclear regulations of the former German Democratic Republic. This mine continues to be used for the deposition and disposal of radioactive wastes under a transitional regulation adopted at the time of German reunification, but it must be re-approved in the next few years.

In the context of a regulatory approval procedure, the Konrad ore mine at Salzgitter is currently being tested as an ultimate disposal site for low-level to medium-level radioactive wastes.

The Gorleben exploratory mine is now being driven in Lower Saxony state. Already approved under mining law, the working is intended to acquire crucial data needed for a proof of concept in the nuclear regulatory approval process for an ultimate disposal facility for highlevel and medium-level radioactive wastes.

10.3. Sealing of Existing Sites

Cutoff Walls. Landfills and abandoned sites often pose dangers to groundwater if appropriate construction techniques (foundation liner, slope seals, etc.) were not employed. To protect the groundwater against possible contamination from these sites, many rehabilitation projects involve constructing cutoff walls around the source of contamination. A cutoff wall has its toe keyed into impermeable soil layers so that it forms a trough-like containment (Fig. 148).

Figure 148. Containment with cutoff walls (thin wall)

Cutoff walls are classified by construction method:

1) Vibrating-beam cutoff walls (thin walls)
2) Slurry walls
3) Soil-mixed walls

Figure 149. Construction of a vibrating-beam cutoff wall

A vibrating-beam cutoff wall is made with vibrating piles; in the other types, an excavator or cutter is used. Vibrating-beam cutoff walls are typically ca. 8 cm thick; maximum depths are around 20 m, and up to 30 m in favorable soil conditions. In building a vibrating-beam wall, the pile is driven to the design depth including ca. 1 m for keying into the impermeable stratum (Fig. 149). As the vibrating pile is withdrawn, the slurry issues at high pressure from the nozzle located at its toe, so that the cavity left by the pile is gradually filled with the cutoff wall slurry. The next cavity is made to overlap the previous one in order to prevent defects in the wall.

1 m^3 of slurry used in a slurry wall usually consists of

25 – 40 kg	bentonite (powdered)
150 – 250 kg	blast-furnace slag cement (HOZ 35 L)
900 – 940 kg	water

In the excavated trench, the slurry first stabilizes the trench itself; afterwards, as setting proceeds, it forms a seamless, impermeable wall. Prepared mixtures with activated bentonite are also available for making cutoff walls. These can be used immediately after dispersing with water and are mainly used in small restoration projects.

Normally, the specifications for restoration work on existing sites call for a permeability $k \leq 10^{-9}$ m/s. If this value is achieved or bettered, the cutoff wall is said to be "structurally tight." An excavated trench wall is also built with a specified amount of overlap between the vertical "lamellae," which depends on the design depth of the trench. The depth of keying in the impermeable bed, generally a clay bed, can be monitored by means of the excavator depth. The approximate topography of the stratum can be determined fairly precisely by borehole tests performed before the construction of the wall proper.

Figure 150. Construction of a cutoff wall by excavation

The following details should be kept in mind during construction:

1) The excavator must be guided vertically
2) The cutoff wall must be keyed into the impermeable stratum
3) The composition of the bentonite-cement slurry must be monitored
4) The attained permeability must be measured

5) The overlap must be checked

Trenches up to 35 m deep can be constructed with the excavator (Fig. 150). If subsoil conditions are favorable, the depth can be extended to 40 m. When even greater depths are desired or ground conditions are poor, as for example when lime benches are present, a rotary cutter can be employed (Fig. 151).

Figure 151. Construction of a cutoff wall with a cutter

The composition of the leachate may lead to impairment or destruction of the cutoff wall slurry. In such cases, cement-free mixtures (e.g., silicate-based) can be used. The initial excavation is carried out in the same way as for a slurry wall; the supporting liquid is then replaced by the wall mixture ("contractor" method). This cutoff mixture is very high in solids (around 90 %), with only the remaining 10 % consisting of liquid. The solid phase of such a cement-free wall is made up of sand and gravel as well as a nonswelling clay to perform the sealing function. The gel-forming liquid phase consists of water, waterglass, and two Dynagrout components. In order to improve safety during construction and operation, cutoff walls can also be built on the "chamber" system (Fig. 152). Parallel cutoff walls (vibrating-beam or slurry or a combination) are constructed around the contaminated region at an interval (ca. 8 – 10 m) dictated by the equipment. Every 50 m, say, or as far apart as 80 m, the cutoff walls are connected by transverse walls made from the same material, so that separate cutoff chambers are obtained. Each chamber has a monitoring well where continuous measurements of water level and water quality can be performed. In this way, the customer is enabled to test the functionality of the containment during construction and also to monitor the wall system during subsequent operation and make certain the cutoff wall system meets requirements. In case of a failure, the defect in the wall can be localized fairly quickly, and the failed chamber can then be repaired.

Figure 152. Chamber system of cutoff-wall containment

The safety standard for containment systems can be further enhanced by hydraulic systems. If the groundwater level inside the cutoff wall is made lower than the level outside the wall, then the operator can be sure that groundwater can move from outside to inside but under no circumstances can contaminated leachate escape from the contaminated region into the groundwater (Fig. 153).

Figure 153. Hydraulic aspects of containment of an existing site (Rautenweg landfill, Vienna)
a) Waste; b) Well, 300 mm diameter; c) Groundwater, upstream; d) Groundwater, downstream; e) Groundwater; f) Sand/gravel; g) Cutoff chamber; h) Double cutoff wall; i) Aquiclude

When safety requirements are more stringent – that is, when the leachate discharge is to be eliminated or when the contaminants present in the leachate are aggressive – composite cutoff walls are built. High-density polyethylene (HDPE) liner material is installed in the slurry while it is still fresh. The liner (standard width 5.00 m) is delivered to the construction site and cut to length, and HDPE connectors are attached to the long edges. The liner material can be stretched over steel frames or unrolled from long rolls and inserted into the excavated trench while the slurry in the trench is still liquid. HDPE is used because it has proved to withstand chemical attack better than other materials. The liner must meet strict physical or physicochemical standards.

There are other engineered alternatives for the containment of existing waste sites, depending on the objective, the geological situation, the composition of the leachate, and other factors. The overlapping cast-in-place concrete pile wall is an example.

Capping Systems. Lining systems known as final covers are constructed to seal hazardous waste sites and also after the closure of landfills. They prevent precipitation percolating into the waste fill and leaching out contaminants. The design varies, depending on the nature and severity of contamination present and, in particular, the solubility of the contaminants in water.

In the case of relatively unobjectionable fills such as construction rubble, slightly contaminated soils, and slightly contaminated power-plant residues, an inorganic material (e.g., clay) provides adequate capping; see Figure 154. If the wastes or residues contain no organic material, the installation of gas drainage can be omitted. The seal system consists of two layers; for reasons having to do with construction technique, this system should have a maximum thickness of 25 cm. In order to produce a ground that is as homogeneous as possible and has the best loadbearing capacity, an equalizer layer is often placed over the contaminated region. The seal proper is overlain by a drainage layer, which should allow prompt removal of water percolating through the recultivation layer. The use of a geotextile between the drainage layer and the seal layer is recommended, and likewise between the drainage layer and the recultivation layer, to ensure the ability of the system to remove water.

Figure 154. Capping system (landfill class I under the TA Siedlungsabfall in Germany)

Figure 155. Composite capping system (landfill class II under the TA Siedlungsabfall in Germany)

If it is necessary to prevent rainwater from entering the fill, composite capping systems are employed (Fig. 155). Such a capping is made up of a mineral seal layer, supplemented by HDPE liners laid directly on the surface of the seal layer. The strips of plastic liner are usually welded by the heated wedge method. The welding of the double seams, with an inspection duct, is done by machine.

The system will be optimally effective if there is an intimate bond between the plastic liner and the mineral seal layer. If the surface is not highly inclined, this is fairly easy to achieve, but in steeper slope regions the construction may present some problems. It is recommended that such cappings be placed only during the warm summer months.

Among the important points for the long-term functioning of a capping system is the maintenance of a relatively high gradient at the surface (e.g., 5 %). This slope should still be present after any settlement has ceased, so that the rapid removal of precipitation can be guaranteed on a permanent basis. The minimum thickness of the recultivation layer is 1 m, though in special cases it may be much greater, for example if a visually appropriate match to the surrounding landscape is desired or if deep-rooted plants are to be grown.

1. Introduction to Drug Discovery and Screening

1.1. A Rationale for new Methods in Drug Discovery

Combinatorial chemistry (→ Combinatorial Chemistry) has been one of the most important keywords in the drug discovery field since the beginning of the 1990s [1–3]. Together with genomics and proteomics [4, 5], the other driving force of the current biotechnology boom, combinatorial chemistry offers the promise of new and better medications. These two new driving forces promise to lead to an explosive increase in both the ability to identify new therapeutic targets (largely thanks to genomics), and the ability to provide tailor-made molecules which can rapidly enter the drug development pipeline (the promise of combinatorial chemistry). The simultaneous, dramatic increase in both the number of targets and potential hit compounds is the reason for what has been called a change in the drug discovery paradigm [6]. To fully capitalize on the promise of both genomics and combinatorial chemistry, the drug discovery process must change in a fundamental way.

Rather than screening 50 chemical compounds against a particular target, combinatorial approaches often require that thousands of compounds be screened. And because of the preponderance of targets, that screening must take place in days rather than months. Out of necessity, high-throughput screening will be a key factor in realizing the potential of new drug discovery strategies by building a bridge between the increased number of targets and the vast number of compounds to be screened.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.b13_b01

Not only does screening throughput need to be increased, but novel assay techniques and detection technologies must be employed in order to provide more information about the suitability of specific compounds earlier in the screening process. This combination of quality and quantity must be achieved in order to fully take advantage of the increased potential for target identification offered by genomics and proteomics and the potential for direct, rapid access to novel chemical compounds offered by combinatorial chemistry and combinatorial biology [7].

By employing new methods for the synthesis of discrete molecules, modern combinatorial chemistry has surpassed the capacity of traditional screening strategies in the search for new active substances. Whether screening libraries of high diversity, such as combinatorial peptide and organic compound libraries, or large libraries of individual natural or rationally designed compounds, modern screening strategies dictate that $10^5 - 10^6$ compounds be screened with a single assay system. Using 96-well microtiter plate automated screening technology, a month would be required to screen 10^5compounds at a rate of 50 plates per day. This rate must be cut by roughly a factor of ten for a laboratory to remain competitive in today's pharmaceutical research environment.

1.2. Sources of Compounds for High-Throughput Screening

Natural product libraries, shelf compounds, libraries from chemically modified natural products and combinatorial compound collections, including peptides, peptidomimetics and small organic molecules, are well established as sources for new lead structures (for a definition of the term lead, see → Combinatorial Chemistry, Chap. 1.). Solution-phase or solid phase synthesis with a variety of chemical reactions and scaffolds allows libraries to be directed at almost any class of targets. Combinatorial chemistry is used in structure-based drug design, for lead optimization and to generate highly diverse compound collections for random screening. Methods for their reproducible, effective and fully automated synthesis and analysis have been established and are dependent on the heterogeneity of the mixtures [8]. As the number of products accessible from a given set of components increases exponentially, synthesis strategies had to be developed that allow the highly parallel and simultaneous production of compounds which were generated and tested as mixtures or as individuals [9]. These strategies are supported by new methodologies for diversity measurement and compound selection [10]. Combinatorial and high throughput synthesis have boosted the generation of compounds in many pharmaceutical companies ten- to fifty-fold.

1.3. Demands on High-Throughput Screening

The diversity of compounds accessible by application of combinatorial chemistry places significant demands on screening strategies. An ideal screening system must provide sufficient flexibility to allow a very large number of individual compounds – at least 50 000 compounds per day – be tested against a variety of targets. The goal must also include the wringing of as much information as possible out of a single library synthesis. Due to the desire to use a library a number of times to maximize the use of each synthesized compound, and synthesis strategies which restrict the amount of compound synthesized per round, it is also necessary that high-throughput screening (HTS) systems are able to operate with low amounts of compound. In order to conserve synthetic reagents and the compounds themselves, and achieve biologically relevant concentrations, modern HTS systems must be able to run several assays with picomole quantities of compound in volumes of less than a microliter: Miniaturization is a prerequisite of an efficient HTS system.

Libraries used for lead finding are by nature diverse, but screening places the added demand that this diversity should be describable: A variety of characteristics associated with each individual compound must be registered and stored, chemical and biological information has to be collated. Not only is it necessary to keep track of each compound, the results of screening must also be tracked for a variety of assays. In the future, efficient integrated synthesis and screening systems will be able to take the stream of

compounds directly from synthesis to screening without the need for interim storage. Hits will be resynthesized in scaled-up quantities for downstream studies based on screening and synthesis information alone.

The assays themselves present a significant demand on HTS systems. Established biochemical assays must be readily adapted to miniaturized format. Additionally, assay throughput can be increased by multiplexing strategies: the rapid sequential or simultaneous detection of multiple parameters. This multiplies the amount of information which can be obtained from a single assay and thereby the information that can contribute to the characterization of a single compound. This also means that the lines between primary and secondary screening will become increasingly blurred (see Section 3.2). A variety of read-out modes must be available in any HTS system, not only to enable assay multiplexing and thereby the rapid and efficient characterization of compounds, but also to allow for flexibility in assay design. This flexibility also contributes to the ease with which specific assays can be translated from standard manual formats to miniaturized automated formats.

EVOTEC's goal is to meet all requirements of HTS through the use of EVOscreen (see Section 3.6) to achieve a degree of sensitivity and specificity through high spatial resolution in miniaturized formats, a multiplicity of read out modes all operating in high-throughput mode, with an integrated database system capable of correlating the data required to obtain useful information.

The challenges of high-throughput screening may be summarized as follows:

- Short measurement times (on the order of 1 s)
- Homogeneous assays: "add & read" format
- Improved speed and ease of assay development
- Use of multi-functional assays
- Early elimination of nonpromising hits
- Biological qualification of early leads
- Real-time data handling and evaluation
- Coefficient of variation (CV) of less than 10 %
- Efficient liquid handling on a nanoliter scale
- Integration of compound storage and testing
- High degree of automation and parallelization
- Modular, integrated system architecture

2. Compounds

2.1. Novel Approaches to Generate Chemical Diversity

The construction of a fully automated laboratory where all manual steps – from chemical synthesis to product characterization – are managed by robots is no longer a futuristic dream. Currently, roughly 20 companies are specialized in the design of chemistry robots of different sizes and levels of automation [11, 12]. The robotized laboratory for chemical synthesis is supported by databases for building blocks, for reaction information and for library information.

Compound mixtures and individual compound collections can be designed for screening either in solution [13], or with compounds immobilized on solid supports, such as polypropylene pins [14], or resin beads [15]. Pharmaceutical companies have started to establish a database for published and proprietary procedures for solid phase organic synthesis which can be downloaded to their automated laboratory for chemical synthesis.

2.2. Microreactor Systems

Today, most combinatorial and high throughput synthesis strategies are calculated for 10 mg, 10 – 20 μM, yield. In the first generation of microreactors, single compound beads or spots on functionalized surfaces have been introduced for the synthesis of pico- to nanomolar amounts of product [16]. As they come into wide use, microreactors will bring about a fundamental change in combinatorial synthesis and screening strategies.

Microreactors are formatted for through-connection to microscale purification units and highly sensitive analytical devices [17] as well as ultra-high-throughput screening (uHTS systems). Nanotiter plates are already being used for direct collection from microfluidic separation units, transferring samples directly to biological assay units. Such integrated labs-on-a-chip – combining microreactors, microscale purification and separation units, and highly sensitive analytical devices – are likely to make

Figure 1. A) Scan of more than 12 000 TentaGel beads using EVOTEC's Bead Scanner/Picker module in the presence of 1 μM fluorescent protein conjugate. B) Close-up of a region of the scan showing the bright fluorescent ring on the positive beads.

compound storage systems obsolete. Test compounds will move directly from synthesis to screening. Furthermore, high-throughput miniaturized synthesis will be designed for parallel synthesis, as well as for the initial scale-up process. To fulfill all of these requirements, all components of integrated microreactors – mixers, valves, and process-control sensors – must be stable to aggressive, highly reactive chemicals.

The benefits of microreactors are many: considerably improved temperature exchange for gas phase reactions; the possibility to carry out the reaction process in an electric field; and simplification of the performance of complex catalytic reactions [18]. These benefits will also provide access to novel chemical structures. Additionally, the bottleneck caused by limited availability of unusual building blocks and scaffolds will be eased or altogether eliminated by microreactor operations and miniaturized screening formats. The advent of microreactor systems for chemical synthesis not only makes direct integration of synthesis and screening possible, but also facilitates the synthesis of novel compounds.

For screening, compounds are removed from the solid support at the point of attachment by cleaving a chemical linker. A variety of chemical linkers have been described, all with the common trait that they enable release of the bead surface compounds under mild conditions (→ Combinatorial Chemistry, Chap. 3.2.1.1.) For identification of specific compounds, several methods for on- or off-bead analysis are available: sequencing of peptides on single beads [16], mass spectrometry of the compounds from one isolated bead [19], chemical tags for decoding by gas chromatography [20], and new tagging strategies, such as DNA tags [21] (→ Combinatorial Chemistry, Chap. 4.2.1.3.) or radiotags (→ Combinatorial Chemistry, Chap. 3.1.1.2.) [22].

Recently, EVOTEC has developed a system for the homogeneous analysis of bead-surface interactions (Fig. 1). This system will enable compound screening to take place without the need to remove compounds from the surface of the bead and thus rapid, on-bead analysis of thousands of beads. Direct recovery of single beads for further analysis is also possible. It eliminates a critical bottleneck, namely the need for deconvolution of solid-phase diversity.

2.3. Limitations of Pooled Compound Screening Strategies

Bioassays are influenced by protein-reactive compounds [23] and tolerate only limited numbers of non-related molecules. False positive and false negative results from screening compound

mixtures have been reported. For example, octa- and hexapeptide mixtures significantly depress binding of the hormone neuropeptide Y to its receptor when measured in a standard competition assay [24].

Many pharmaceutical companies own sample collections of up to a million individual natural or synthetic substances. Combinatorial libraries will enlarge the collections to several million compounds. This explosion in the number of samples and the associated assay costs have forced most screening units to resort to a pooling strategy whereby sometimes thousands of samples are mixed in a single well for primary screening in traditional 96-well formats. This pooling strategy makes the results of screening difficult to interpret, but it is currently the best way to meet necessary throughput levels with conventional assay formats. Different pooling strategies have been experimentally compared using a library of 810 phosphate diester-linked peptide trimers. The results showed that random pooling, positional scanning, and iterative methods identified the same active compound [25]. But applying an artificial procedure where the best compound was hidden in a pool of least active compounds failed to identify the optimal trimer structure [25]. This is the primary reason behind the drive to miniaturization and increased throughput. The screening systems of the future must not only be faster, they must provide more reliable data and be more economical.

3. Screening Technology

3.1. Chemistry, Biology, and Technology

At the screening rates enabled by high and ultra-high throughput applications, reagent consumption is a critical factor. By reducing the volume of reagent required for synthesis and the amount of compound required for analysis, miniaturization during both synthesis and screening phases can lead to significant savings over current methods [26]. Additionally, given the number of compounds to be screened, often of similar chemical structure, novel assay techniques and detection technologies must be employed in order to provide better characterization of specific compounds, and this earlier in the screening process. A collection of synthetic compounds is likely to be used in several different assays – another reason to keep reagent consumption to a minimum. Multiplexing strategies, whereby multiple parameters can be measured by employing multiple assays and/or read-outs in a single sample, will also improve screening efficiency. This combination of quality and quantity must be achieved in order to fully take advantage of the increased potential for target identification offered by genomics and proteomics and the potential for direct, rapid access to novel chemical compounds offered by combinatorial chemistry and combinatorial biology [26]. High- and ultra-high-throughput screening will not only allow realization of the potential of these new technologies, it will also enable better usage of natural compound libraries, long a primary backbone of drug discovery. Screening, therefore, is the link between biology (targets) and chemistry (drug-like molecules). And in the age of genomics and combinatorial chemistry, that link must achieve high throughput. Figure 2 (see next page) illustrates the unification of targets, compounds and assays in screening applications for drug discovery.

The effective use of high-throughput screening for combinatorial applications depends on effective synergy between the traditional disciplines of drug discovery, namely biology, biochemistry, and chemistry, and the technologies associated with combinatorial chemistry [27] and such diverse disciplines as information technology, robotics, physics, and liquid handling. Screening was once the exclusive province of large pharmaceutical companies. Today, screening is increasingly carried out by alliances between biotech ventures, devoted to developing screening strategies, and research laboratories, whether they be large pharmaceutical firms or other biotech ventures, who provide a specific target for screening.

3.2. Primary, Secondary, and Tertiary Screening

Drug screening has traditionally been divided into three phases: primary, secondary and tertiary. In the primary phase, a biological target (often referred to in the pharmaceutical industry as a therapeutic target) is screened against

Figure 2. The integration of the three primary components of drug discovery screening: compounds, targets, and assays.

a large number of compounds in a biological assay with the aim of finding hundreds or thousands of compounds which interact (usually in the form of binding) with the target [28]. Compounds selected in the primary screen, usually designated "hits" for a particular target, then enter the secondary phase of screening. In the secondary phase of screening, each hit is characterized as to a range of biological parameters, such as solubility, toxicity, etc. The secondary phase of screening is also where the process of hit optimization occurs, often using focused or directed libraries of structurally-related chemical compounds. The compounds that emerge from the secondary round of screening are then labeled "leads" to designate their status as potential drugs. In the tertiary rounds of screening, compounds are screened for a variety of parameters important to use as a medication: ease of uptake, speed and breadth of distribution throughout the body, modes of metabolism and excretion, and pharmacokinetics. Each phase of this screening process lasts several years in current practice with the entire drug discovery process typically spanning eight to twelve years.

As a result of the dramatic increase in targets and compounds to be screened, traditional screening is currently undergoing a reevaluation. In addition to the move to miniaturization and increases in throughput, increased efficiency is also called for. One way to increase efficiency is to obtain more information at an earlier stage of drug screening.

Primary screening is largely the establishment of a structure-activity relationship (SAR). At this stage of screening, several strategies are typically employed to manage the biological testing of large chemical compound sets against multiple biological targets. Bioassays typically take the form of a competitive binding reaction [28]. For this purpose, the evaluation of a single compound per bioassay per well provides the most unambiguous information and this is precisely why throughput must be increased. The advantages are clear: with a single compound per well, no deconvolution is required and minimal potential for "masking" of bioactivity exists. With one compound per well, the primary bioassay provides extensive structure activity relationship data and additional information for subsequent lead optimization activities. Miniaturization and automation are required to reduce the cost of this approach compared to the alternative strategy of "compound pooling". While the pooling of 3 – 10 compounds per bioassay has been utilized to quickly and efficiently assay large sets of compounds, the primary disadvantage is the need for subsequent deconvolution of positive read-outs, and the potential for masking of one compound's activity by others. By maintaining the one-compound-per-well configuration, the maximum amount of information can be obtained per compound.

Secondary Screening. In secondary screening, multifunctional testing for parameters such as selectivity, toxicity, dose-response is con-

ducted. By combining miniaturization, automation, and multiple detection modes, this process can be moved forward in the drug screening process. New read-out technologies will enable several parameters to be measured simultaneously meaning that assays, rather than compounds, will be "pooled" in a single screening run. Just as conventional strategies led to the pooling of compounds to increase throughput, new detection technologies enable far more information to be obtained in a single measurement, leading to an increase in information and a shortening of screening time. This will make lead evaluation feasible in early stages of the drug discovery process.

Tertiary Screening. Novel types of assay can also be designed for tertiary screening: the profiling of compounds to obtain valuable biological information, such as bioavailability and cellular uptake. To predict whether a molecule has the potential for in vivo pharmacological activity, it is necessary to determine whether the molecule persists in the body long enough at concentrations sufficient to exert the intended pharmacological effect. Such evaluations hinge on assessments of absorption, distribution, metabolism, excretion and pharmacokinetics (ADME/PK). If these evaluations are made in the early stages of drug discovery, resources can be appropriately channeled to those molecules that are likely to succeed in terms of in vivo efficacy. Moreover, where a series of lead compounds is identified by in vitro pharmacological testing, AMDE/PK provides a means of rank-ordering the compounds based on characteristics essential to an effective medication. Such tertiary screens are typically carried out in test animals or in living cells. New detection technologies are being used in functional cellular assays to explore signal transduction, transcriptional control, and even cellular viability. The availability of human liver tissues, cell culture systems (e.g., Caco-2) as a model of the intestinal mucosa, recombinant drug metabolizing enzymes, and cytochrome P450 isoform-selective substrates and inhibitors have provided the tools to effectively conduct such in vitro studies.

Blurring the Lines Between Primary, Secondary, and Tertiary Screening. Because of the difficulty of working with living cells, as well as the difficulty in automating functional assays, cellular assays have been relegated to smaller screens much later in the discovery process. The need to increase the screening speed and the type of information derived means that assays using living cells are now even being used in primary screens. Most assay strategies for use in living cells rely on genetically manipulated (recombinant) cells. However, such over-expressing recombinant cell lines frequently have altered physiological properties compared to primary or nonrecombinant cells, particularly with regard to regulatory mechanisms of signal transduction. Thus they cannot be considered to be ideal for this purpose. For cellular assays, miniaturized systems are capable of providing a superior solution: the combination of sensitivity and miniaturization enables primary cells to be employed. The restrictions resulting from the availability of primary cells are overcome by the very small number of cells needed for each assay (100–1000 cells per well).

3.3. Miniaturization, Automation and Homogeneous Assays

Miniaturization is an inherent characteristic of most modern high-throughput screening systems, but the detection technology is often largely unchanged from many of the read-out technologies used in conventional assays. To provide the most effective synergy between screening technology and assay development, screening systems must provide detection technology which is matched to the demands of miniaturization, on the one hand, and offers significant flexibility of read-out methods, on the other. To fully exploit the advantages offered by miniaturization and enable the highest throughput possible, modern high-throughput screening systems must possess a high degree of automation. The need to precisely deliver assay components in sub-microliter quantities requires not only high-precision liquid handling systems, but automated control of such systems since the volumes handled can barely be seen with the naked eye, much less manually pipetted.

Homogeneous assay methods have been developed which enable "add & read" strategies to be employed. In such homogeneous systems,

no washing, concentration, or separation steps are required. The read-out technologies employed for such systems are discussed in Section 3.4. All assay components, including the target and the compound to be screened, are added to a single well in which the interaction is directly evaluated. Homogeneous methods have been developed to assay the following biological parameters:

1) Molecular binding events: the study of the binding kinetics of molecular interactions, such as receptor-ligand, protein-protein, protein-nucleic acid, and nucleic acid-nucleic acid
2) Molecular processing: the evaluation of the progression and outcome of enzymatic action in assays designed to measure such properties as aggregation, polymerization, degradation, or enzymatic modification of proteins or nucleic acids
3) Vesicular and cellular events: the study of cellular systems for the evaluation of transcriptional activity, signal transduction, membrane-bound or cytoplasmic reactions (potentially involving intracellular navigation), etc.

3.4. Detection Technologies for High-Throughput Screening

Fluorescence-based detection technologies are the method of choice of most modern high-throughput screening systems. Assays based on the use of radioactive tagging, however, still predominate in the area of diagnostics. This is because of a fundamental difference in the types of assays called for in screening and diagnostics. Diagnostic assays require the use of heterogeneous assays (marked by the inclusion of steps to separate unused ligand) to achieve a wide dynamic range of detection and high sensitivity. In screening, on the other hand, the establishment of the structure-activity relationship is accomplished in competitive binding assays readily adaptable to homogeneous formats [28]. For this reason, the use of fluorescent dyes has effectively replaced radioactivity as the tagging method of choice for high-throughput biological assays [29].

The ability to make full use of the fluorescent molecule and all of its properties should be the benchmark of any fluorescence-based assay technology. While most assay strategies make use of only a single fluorescent property, the broad applicability of a screening system requires that flexibility of assay design be extended to the read-out technology by including a variety of detection modes. Although the use of fluorescence in biological assay systems is frequently restricted to the measurement of fluorescence intensity, the measurement of additional fluorescent properties, such as lifetime, polarization, fluorescence energy transfer and quenching can yield a wealth of information from a single measurement. This ability to collect multiple data points per measurement not only provides an internal control, but also contributes to screening efficiency by enabling rapid multi-parameter evaluation of compound-target interactions.

In addition to the use of fluorescence tagging, confocal microscopic optical systems form the foundation of many modern read-out technologies. Using confocal optics, sub-microliter miniaturization may be accomplished without any loss of signal quality. The highly-focused confocal optics reduce the detection volume to as little as one femtoliter. This means that the detection volume, roughly the size of a bacterial cell, is much smaller than a eukaryotic cell or standard miniaturized assay volumes of one microliter. Whereas other methodologies often suffer from the increased contribution of surface effects and from drastically reduced signal-to-noise ratios when assay volumes are reduced, the confocal optics eliminate such limitations. Furthermore, confocal detection technology enables the use of homogeneous assay methods, i.e. those which eliminate washing or so-called "sandwich" strategies (i.e., increasing the assay signal by "sandwiching" the analyte between multiple binding molecules, such as antibodies, necessitating multiple steps of washing). This is a great advantage in screening in that it allows biological systems to be evaluated in close to their natural in vivo state.

Table 1 lists a variety of different fluorescent parameters used as read-out modes for biological assays and their areas of application. Though this list is by no means exhaustive, it gives an indication of the wide variety of information ac-

cessible through fluorescent measurement methods.

Table 1. Multifunctional analysis by confocal fluorescence detection

Detection value	Analytical information
Translational diffusion	molecular mass, shape, binding events, microenvironmental viscosity, oligomerization
Confocal fluorescence lifetime	conformational changes, binding events, potential, electronic environment
Fluorescence depolarization/correlated rotational diffusion	conformational changes, binding events
Fluorescence resonance energy transfer	proximity
Multicolor assays	cellular navigation, multiparameter testing, multiple binding events
Fluorescence recovery after photobleaching	functional reporter binding, membrane fluidity
Fluorescence cross-correlation	molecular mass independent molecular interactions (protein – protein, protein – nucleic acid, nucleic acid – nucleic acid)
Particle number	enzymatic reactions
Triplet transition probability	electronic environment

3.5. Examples of Specific Fluorescence Detection Technologies for High-Throughput Screening

Fluorescence correlation spectroscopy (FCS) takes advantage of differences in the translational diffusion of large versus small molecules [30, 31]. Each molecule which diffuses through the illuminated confocal focus gives rise to bursts of fluorescent light quanta during the entire course of its journey, with each individual burst being registered. The length of each photon burst corresponds to the time the molecule spends in the confocal focus. The photons emitted in each burst are recorded in a time-resolved manner by a highly sensitive single-photon detection device. This detection method achieves single molecule sensitivity, but the fact that diffusion is a random process requires that the diffusion events for a minimum ensemble of molecules be averaged to achieve statistically reliable information. The detection of diffusion events enables a diffusion coefficient to be determined. This diffusion coefficient serves as a parameter to distinguish between different fluorescent species in solution, for example between free or bound ligands. In screening, the diffusion coefficient can be used to determine such factors as concentration or degree of binding. Hereby, confocal optics eliminate any interference from background signals and allow homogeneous assays to be performed. FCS measurements are conducted in a matter of seconds making the technology ideally-suited for high-throughput application [32]. For example, using FCS, not only can a structure-activity relationship be determined between the compound and target, but also the concentration can be determined in a single measurement. This enables dose-response to be evaluated immediately during screening.

Fluorescence resonance energy transfer (FRET) is gaining increasing acceptance as a nonradioactive assay method for screening [33, 34]. FRET capitalizes on the transfer of energy from one fluorescent molecule to another. The distance between fluorescent molecules must be less than 4 – 5 nm [35], which is approximately the diameter of a protein molecule with a molecular mass of 26 000. A major consideration in choosing an assay based on energy transfer is the change in distance that is induced upon ligand binding or enzyme turnover. For example, FRET can be employed for protease assays using peptide substrates labeled with two fluorescent dyes, whereby energy is transferred from one dye to the other. Upon digestion with a protease, the two fluorescent molecules are brought out of close proximity and the loss of fluorescence intensity is measured. Again, using confocal optics, homogeneous assays can be performed using this read-out technology.

Fluorescence Polarization (FP). Since 96-well FP readers have become commercially available, FP has gained importance for screening. The advantages of FP include the need for only one fluorescent label and the easy adaptability to homogeneous assay schemes [36, 37]. In FP, changes in the polarization of fluorescent molecules are measured. As a molecule rotates, the polarization of an attached fluorescent tag can be determined. When such a molecule binds to another, its rotational movement, and thereby the frequency in its changes in polarization, are restricted. Since the polarization shift taking place upon excitation of the fluorophore

is proportional to the fraction of the total fluorophore in the bound state, receptor – ligand assays may need to be performed in the presence of excess receptor, a situation that is not always practical. Enzymes, primarily proteases, but also kinases and phosphatases can also be assayed using FP. Compared with FRET, FP is more useful when the targets are large, since larger changes in rotational mobility can generally be observed. Many manufacturers of FP readers are developing readers compatible with 384-well plates and even higher density formats – opening the way for applicability of this read-out mode to HTS.

Time-Resolved Fluorescence. The analysis of time-resolved fluorescence in homogeneous assays (HTRF) is rapidly gaining acceptance in HTS [29]. The time-resolved analysis of fluorescent emission in bioassays has been made possible by the use of the specific properties of lanthanide ions, especially europium, terbium, samarium, and dysprosium ions. These ions possess unique properties which make then especially attractive for bioassays: they are hydrophilic and have long excited-state lifetimes which enable them to be easily distinguished from other sources of fluorescence emission in a homogeneous sample [28]. Using these lanthanide ions, in the mid-1990s homogeneous assays have been developed for application to HTS [38]. By labeling one component of a competitive binding bioassay with one of these ions, read-out methods are being developed for a range of assays based on the time resolved analysis of fluorescence [28]. Readers are already under development by several companies for densities of up 864 wells in a microtiter plate format. The expense of the ions used for this method is, however, one factor which must be considered in the move to high-throughput applications.

Fluorescence Imaging. By the development of highly sensitive detection systems, imaging technology has become of use in drug discovery. Although this type of detection is based on the measurement of intensity alone, images can be acquired in quick succession enabling rapid changes in cells to be observed. The development of a commercial high-speed, high sensitivity imaging system [39], enabled limitations in the detection of calcium flux to be overcome (the calcium response is short lived, < 1 s). This imaging system is able to collect parallel image data at speeds up to 10 frames per second, at sensitivities that allow detection of calcium transients in cell populations. High-sensitivity fluorescent imaging plate readers have been developed for cellular assays, particularly assays of membrane potential and intracellular calcium release [40]. The instrument uses a high-intensity laser source with narrow depth-of-field optics which helps to eliminate background signals. The combination of fluidics and imaging allows for high-throughput despite the transience of the response. Although fluorescence imaging is widely used, particularly for cellular assays, the influence fo non-specific adsorption effects and variations in signal due to small differences in filling levels limit its application in solution-based assays.

3.6. Case Study EVOscreen

EVOTEC BioSystems has developed a unique platform integrating highly sensitive detection technology and high-precision liquid handling systems in a modular system which will be capable of handling 100 000 assays per day. The core elements of the modular system are: A high performance confocal fluorescence detection unit usable in either a single channel or multi-channel mode; proprietary signal processing protocols based on FCS, and related single molecule-based confocal fluorescence methodologies enabling read-out of fluorescence polarization, lifetime, and intensity; a miniaturized, automated liquid handling system for nano- to low microliter volumes (including pipetting, dispensing and compound retrieval); a rapid, miniaturized multi-replica compound repository providing the link between traditional single-compound library formats and EVOscreen; a micro-separation device (HPLC) coupled to the detection system; and a scanner and picker device for the analysis of combinatorial libraries and for functional genome analysis.

Liquid Handling. The ability to miniaturize assays to the sub-microliter level is largely dependent on the precision of liquid handling systems. Modern pipetting and dispensing systems enable components to be reproducibly

Figure 3. A) Comparison of the reduction in space achieved by using miniaturized sample carriers. 2000 samples may be carried by either the 23 microtiter plates seen in this picture, or a single 2000-well nanocarrier seen in the lower right
B) The head of a nanodispenser over one of the wells of a 2000-well nanocarrier.

added in volumes in the nanoliter range to thousands of samples per plate. The EVOscreen system includes a specially designed micro-to-nano (M2N) unit which is able to reformat samples stored in any conventional format, such as 96-well plates, to the high-density 2000-well nanocarriers (see Fig. 3) used for miniaturized assays. Also included is an automated storage and retrieval system providing a compound repository, as well as transport mechanisms for the many millions of compounds to be used in the screening runs. One specific feature of the EVOscreen liquid handling system is single-drop monitoring and on-line quality assurance.

Acknowledgements. The authors would like to thank Drs. Rolf Günther and Eloisa Lopez-Calle for reviewing the manuscript and for helpful discussions.

By application of metallocenes a new catalyst family has been introduced into polyolefin production, the most quickly growing market in the polymer industries. The easy modification of the metallocene catalyst structure brought about improvements in catalyst activities, comonomer incorporation, and polymer properties. It became possible to tailor in a wide range the microstructure of polyolefins such as chain length, molecular mass distribution, polypropylene tacticity, and comonomer distribution.Ethylene/oct-1-ene and cycloolefin copolymers, syndiotactic or isoblock polypropylenes and syndiotactic polystyrene are some types of new industrially produced polymers. The polyolefins synthesized by metallocene catalysts show a narrow molecular mass distribution of 2 and in some cases long chain branches.

1. Introduction

Metallocene – methylaluminoxane (MAO) (→ Aluminum Compounds, Organic) catalysts have opened a frontier in the area of organometallic chemistry, polymer synthesis and processing [1, 2]. A great number of different titanocenes zirconocenes, and hafnocenes have been synthesized that produce tailored polymers of totally different structures and make the control of polymer tacticity, molecular mass and molecular mass distribution more efficient. New kinds of homopolymers, copolymers and elastomers can be produced [3 – 5].

Metallocene catalysts are soluble in hydrocarbons. These catalysts show only one type of active site (→ Polyolefins) and their chemical structure can be easily changed. This allows (1) an accurate prediction of the properties of the resulting polyolefins by knowing the structure of the catalyst used during their manufacture and (2) the control of the resulting molecular mass and mass distribution, comonomer content and tacticity by careful selection of the appropriate reactor conditions. In addition, the activity of these catalysts is ten to hundred times higher than that of the classical Ziegler – Natta systems. Metallocenes, in combination with the conventional aluminumalkyl cocatalysts used in Ziegler systems, are indeed capable of polymerizing ethylene, but at a very low activity. Only with the application of methylaluminoxane was it possible to enhance the activity by a factor of 10 000 and more [6, 7]. Therefore, MAO plays an crucial part in the catalysis with metallocenes.

Methylaluminoxane is a compound in which aluminum and oxygen atoms are arranged alternately and free valences are saturated by methyl substituents. It is produced by careful partial hydrolysis of trimethylaluminum (→ Aluminum Compounds, Organic, Chap. 3.1) and, according to investigations by Sinn [8] and Barron [9], it consists mainly of units of the basic structure $[Al_4O_3(CH_3)_6]$, which contains four aluminum, three oxygen atoms and six methyl groups. As the aluminum atoms in this structure are coordinatively unsaturated, the basic units join together forming clusters and cages. These have molecular masses ranging from 1200 to 1600 and are soluble in hydrocarbons.

If metallocenes, especially zirconocenes, are treated with MAO, catalysts are obtained that allow the polymerization of up to 100 t ethylene

per gram of zirconium. At such high activities (i.e., small quantities of catalyst required) the catalyst can remain in the product. The insertion time (time needed for the insertion of one molecule of ethylene into the growing chain) amounts to some 10^{-5} s only.

It is generally assumed that MAO first undergoes a fast ligand exchange reaction with the metallocene dichloride, thus forming the metallocene methyl and dimethyl compounds. In a second step, either Cl^- or CH_3^- is abstracted from the metallocene compound by an Al-center in MAO, thus forming a metallocene cation and a MAO anion [10, 11]. The alkylated metallocene cation represents the active center. Meanwhile, other weakly coordinating cocatalysts, such as tetra(perfluorophenyl)borate anions $[(C_6F_5)_4B]^-$, have been successfully applied to the activation of metallocenes [12 – 14].

Methylation

Activation

Further milestones were reached in 1982, when Brintzinger [15] synthesized chiral bridged metallocenes and in 1984, when Ewen [16] demonstrated that partially isotactic polypropylene can be produced with appropriate titanocene catalysts. Highly isotactic material was obtained with analogous zirconocenes [17]. After this discovery, an avalanche-like development of industrial and scientific research in the metallocene sector commenced.

Polyolefins, with different microstructures and characteristics, can be custom-made just by varying the ligands of the metallocene (Table 1) [18, 19]. By combining different olefins and cycloolefins with one another, the range of characteristics can be broadened further.

Using metallocene catalysts, it was possible for the first time to produce polyethylenes, polypropylenes, and copolymers with narrow molecular mass distributions ($M_w/M_n = 2$) [6, 21], syndiotactic polypropylene (in technical scale amounts) [22], syndiotactic polystyrene [23], cyclopolymerizates of 1,5-hexadiene [24], cycloolefin copolymers (COC) with high catalytic activity [25], optically active oligomers [26] and composite materials of biomass, powdered metals, nanoparticles, and polyolefins [27].

Figure 1. Microstructures of polypropylenes of different tacticities, modified Fischer projection.

2. Polyethylene and Polypropylene

The polymerization of ethylene and propene with selected metallocenes under identical conditions is summarized in Table 2. It is evident that the unsubstituted zirconocene Cp_2ZrCl_2 (**1**) has a high activity in the polymerization of ethylene. Hafnocenes are less active than analogous zirconocenes. Surprisingly, the sterically congested and highly substituted metallocene **11** (see Table 1) displays the highest activity in the polymerization of ethylene among the compounds listed in Table 2 [28]. This leads to the conclusion that electronic effects are particularly important for the insertion reaction. The molecular mass of polyethylene and polypropylene (PP) can be adjusted to lower values by raising the polymerization temperature, by addition of small amounts of hydrogen, or by decreasing the monomer concentration. Apart from isotactic and atactic polypropylene, also syndiotactic and the isoblock and stereoblock materials can be synthesized for the first time in large quantities and high purity (Fig. 1). Syndiotactic polypropylene can be synthesized by complexes containing fluorenyl and cyclopentadienyl ligands bridged by X (compounds **15** – **17**, Table 2) [22]. The block lengths of equal tacticity in isoblock PP (in which the methyl groups extend in one direction) can be varied in a broad range on the nanoscale (4 – 100 units). This leads to microcrystalline PP which is suitable for production of transparent films. The development of applications for elastic stereoblock PP has just begun [29, 30].

By inserting a silyl bridge and substituting the indenyl ligands in zirconocene **1**, the group at Hoechst in Frankfurt and BASF in Ludwigshafen were able to enhance the activity and stereoselectivity of the isotactically working catalyst considerably (compounds **11** – **13**). These catalysts afford isotactic PP of high molecular mass and a melting point of 161 °C [31]. Polypropylenes made by metallocenes exhibit distinct differences to conventionally produced polypropylenes, such as narrow molecular mass distributions, higher stiffness, and greater tensile strength. This is caused not only by the more uniform structure but also by the extremely low fractions of oligomeric products with low molecular mass. These fractions amount to less than 0.1 %, compared to 2 – 4 % in Ziegler – Natta PP. Copolymers of ethylene and oct-1-ene produced by analogous "single site" catalysts **14** of Exxon and Dow in the USA (→ Polyolefins) have already established a market in the packaging industry and in the field of medical applications [32].

Metallocene catalysts will become extremely important in the manufacturing of elastomers with elastic properties similar to rubber. The copolymers of ethylene and propene with a molar ratio of 1 : 0.5 to 1 : 2 are of great industrial interest. These ethylene – propene (EP) polymers

show elastic properties and, together with 2 – 5 wt % of dienes as third monomers they are used as elastomers (EPDM) [33, 34] (→ Rubber, 3. Synthetic). One of the biggest industrial plant with a capacity of 400 000 t/a for ethylene – propene copolymers was erected by Nova Chemicals, Canada.

The regiospecificity of the metallocene catalysts in regards to propene leads exclusively to the formation of head-to-tail enchainments. 5-Ethylidene-2-norbornene, for example, polymerizes via vinyl polymerization of the cyclic double bond and the tendency to branch is low.

High branching, which is caused by the incorporation of long-chain olefins into the growing polymer chain, is obtained with a new class of silyl bridged amido(cyclopentadienyl)titanium compounds **14** [35]. These catalysts, used by Dow and Exxon in combination with MAO or borates, incorporates oligomers with vinyl endgroups, which are formed during polymerization by β-hydrogen transfer, resulting in long chain branched polyolefins [32].

Long branched copolymers of ethylene with oct-1-ene (polyolefin elastomers, POE) show elastic properties as long as the oct-1-ene content is > 20 % [36]. Other elastomers with different microstructures can be synthesized from dienes [37].

3. Cycloolefin Copolymers

Metallocene catalysts are particularly important for the polymerization of cycloolefins (cyclopentene, norbornene and their substituted compounds). In this process, only the double bond is opened and not the ring. Crystalline polycycloolefins have extremely high melting points of at least 380 °C, being sometimes higher than the decomposition temperature [38 – 40].

While homopolymerization of cyclopentene results in 1,3-enchainment of the monomer units norbornene is inserted in 1,2-enchainment as is usual for polymerization of olefins [41].

The problems of processing that arise from the high melting temperatures of cyclopentene and norbornene homopolymers can be solved by copolymerizing cycloolefins with ethylene, for example. The insertion of norbornene units into the growing polymer chain proceeds very easily. The copolymerization parameter r_1 determines how much faster ethylene is inserted than norbornene if the last monomer unit inserted was ethylene. The value of r_1 is only between 2.0 and 3.4 which shows that it is easy to incorporate this huge monomer. Table 3 compares activities and the incorporation of norbornene for different catalysts.

The metallocene [Me_2C(*tert*-BuCp)(Flu)] $ZrCl_2$ **18** shows not only high activities for the copolymerization of ethylene with norbornene,

Table 3. Copolymerization of norbornene (Nor) and ethylene by different metallocene – MAO catalysts at 30 °C *

Catalyst	Time, min	Activity, kg $mol^{-1}h^{-1}$	Incorporation of Nor, %
Cp_2ZrCl_2	30	1 200	21.4
$[En(Ind)_2]ZrCl_2$	10	9 120	26.1
$[Me_2Si(Ind)_2]ZrCl_2$	15	2 320	28.4
$[En(IndH_4)_2]ZrCl_2$	40	480	28.1
$[Me_2C(Flu)(Cp)]ZrCl_2$	10	7 200	28.9
$[Ph_2C(Flu)(Cp)]ZrCl_2$	10	6 000	27.3
$[Ph_2(Ind)(Cp)]ZrCl_2$	15	2 950	33.3

* Conditions: MAO/Zr = 200, [Zr] = 5×10^{-6} mol/L; ethylene pressure: 2 bar, [Nor] = 0,05 mol/L. Cp = Cyclopentadienyl. En = Ethenyl. Ind = Indenyl. Flu = Fluorenyl.

but also effects an alternating structure in the polymer [42].

It is impossible to produce copolymers with more than 50 mol % of norbornene. The melting point of the alternating copolymer depends on the molar ratio of norbornene units in the polymer while the glass transition temperature is nearly independent on this value. A maximum melting point of 320 °C was achieved.

Cycloolefin copolymers (COC) have an excellent transparency and a very high continuous service temperature. From cycloolefin insertion rates of 10 mol % upwards, these copolymers are no longer crystalline but amorphous. They are very resistant towards solvents and chemicals, they exhibit high softening temperatures (glass temperatures of up to 200 °C) and can be processed like thermoplastics. A further peculiarity of these materials is their extremely low light absorbance, which makes them suitable for optoelectronic applications. Norbornene – ethylene copolymers are most interesting for technical uses because of the easily available monomers. Such COC polymers have already been used for the production of compact discs in Japan and films in Germany. 30 000 t/a of COC materials are produced by Ticona, Germany. Applications for optoelectronic data transfer and storage as well as for other areas of high technology have been provided for.

4. Syndiotactic Polystyrene

Idemitsu was able to demonstrate that especially titanium compounds combined with MAO are capable of polymerizing styrene in a syndiotactical manner [23]. Moreover, cyclopentadienyl titaniumtrichlorides ($CpTiCl_3$) have been proven to be remarkably active catalysts in this case [43]. Syndiotactic polystyrene is crystalline and has a melting point of 275 °C, which nearly makes it a high performance plastic.

If fluorinated complexes are employed such as pentamethylcyclopentadienyl titaniumtrifluoride, the activity can be improved by a factor of 30 [44] compared to chlorinated compounds. At the same time the molecular mass rises from 169 000 to 660 000.

The copolymerization of styrene with ethylene, as examined by MÜLHAUPT, leads to new copolymers with special properties and applications [45]. Syndiotactic polystyrene has already been produced in technical amounts by Idemitsu and Dow.

5. Supporting of Metallocene Catalysts

Only few polymerization processes use metallocene catalysts in a homogeneous form. Supported metallocene catalysts are preferred for the production of polyethylene or isotactic polypropylene on an industrial scale. In order to use them in existing technical processes (drop-in technology) by exchanging the conventional Ziegler – Natta catalysts, the metallocenes have to be applied to a powdery, insoluble substrate. Therefore, the metallocenes have to be absorbed on silica, alumina, magnesium dichloride or other supports. Different methods are possible [46 – 52], for instance: (1) initial absorption of MAO on the support with subsequent addition of metallocenes in a second step, which is most frequently used. These catalysts are used in combination with additional MAO or aluminum alkyls in the polymerization. (2) Another way is either absorption and immobilization of the metallocene or covalent bonding by a spacer to the

support surface as the first step. Then, after addition of MAO, this catalytic system is used in the polymerization process. Both procedures afford different catalysts and these, in turn, produce polyolefins with different properties.

The polymers obtained by method (1) are very similar to those obtained by the homogeneous system. Each metallocene on the support forms an active center and the starting point for the growth of a polymer chain. As the active sites on the surface of each catalyst grain are identical, all chains grow uniformly resulting in polymers with narrow molecular mass distributions. If the metallocene is linked to the support first, different types of absorption occur. In addition, a large part of the metallocene is destroyed by acid centers. The different absorption bonds lead to different active sites. Therefore, the activity is much lower than in the case of the homogeneous system and the molecular mass distribution of the polymer produced is much broader.

In the late 1990s other complexes of early transition metals such as titanium, zirconium, and chromium were discovered for the active polymerization of olefins [53]. In these complexes the central atom is surrounded by salicyl aldimine or imino phenolate ligands. Other new complexes were those of late transition metals — nickel, palladium, cobalt, and iron — with diimine ligands [54]. All these catalyst complexes need MAO or fluorinated borates for activation similar to metallocenes.

1. Introduction

In the last two decades powerful processes have been developed for the fabrication of three-dimensional microdevices from a wide variety of materials. These processes include:

- Bulk micromachining of monocrystalline materials, e.g., silicon, by anisotropic wet chemical etching [1]
- Dry etching with low-pressure plasma or ion beams (reactive ion etching, reactive ion beam etching) [2]
- A combination of deep lithography, electroforming, and molding (LIGA process) [3]
- Micromachining with laser radiation [4], [5]
- Anisotropic etching of photosensitive glass [6]
- Advanced mechanical milling, turning, sawing, and drilling processes based on precision engineering [7–11]
- Isotropic wet chemical etching, e.g., of metal foils with a resist pattern [12]
- Micro spark erosion [13], [14]
- Various rapid prototyping processes based on laser-assisted polymerization [15]

Usually, several technologies are combined in a process line for fabricating microdevices and can be regarded as machines in a microworkshop, which also includes auxiliary processes ranging from thin-film technology to mechanical surface modification, as well as test equipment and design and simulation software.

As a result of these microfabrication processes, microminiaturization is no longer exclusively a realm of microelectronics. Mechanical,

optical, thermal, and fluid microdevices are a part of our daily life and include laser heads for CD players, read/write heads for hard disks, microsensors in automobiles, ink jet printer heads, and minimum-invasion surgical instruments [16]. Recently, microdevices have also become of interest for chemical, pharmaceutical, and biotechnical applications [17–28].

In accordance with the term microsystem, which is now widely accepted, microreactors usually are defined as miniaturized reaction systems fabricated, at least partly, by microtechnology and precision engineering. The characteristic dimensions of the internal structures of microreactors such as fluid channels typically range from the sub-micrometer to the submillimeter regime. The terms nanoreactors and milli-/minireactors are sometimes used for devices with characteristic dimensions at the lower and upper limits of this dimensional range. In this article, however, only the term microreactor is used.

Microreactors can be constructed from single components or as integrated systems. Components mainly perform a single operation, mostly a unit operation such as mixing, heat exchange, or separation. The majority of microfluidic devices belong to this group [26]. Since more than one (unit) operation is generally necessary to give the desired effect, many applications require more complex systems, known as integrated microreaction systems. Here components are assembled to form a complete and complex unit, so that macroscopic channels are only found at the end and beginning of the system, while fluid channels in the system have diameters in the micrometer range.

The potential advantages of microreactors compared to macroscopic reaction systems include the following:

- Faster transfer of research results into production
- Earlier start of production at lower costs
- Easier scale-up of production capacity
- Smaller plants for production at distributed sites
- Lower costs for transport, materials, and energy
- More flexible reaction to market demands

Microreaction technology is sometimes regarded as a key strategy for economic growth, by means of cost and time saving, and for the ecology, by sustainable development and saving of natural resources.

In the field of life sciences, commercialization has already been achieved. Several billion compounds have been screened in drug-development programs, and not only 1536-well titer plates but highly sophisticated microsystems for high-throughput synthesis and screening have reached a rapidly expanding market (→ High-Throughput Screening). Immunoassays on integrated optical wave guides and combinatorial DNA analysis and parallel polymerase chain reactions on a chip have become reality.

In chemistry, however, the advantages of miniaturization and the challenge of microreaction engineering have only recently been recognized and inevitably the information is rather limited. The first prototype microreactors for chemical processes were built [20], [27], [28] and tested [20], [29], [30] in the early 1990s. In addition, components of interest for chemical microreaction engineering but developed for other applications were described as early as the 1980s and early 1990s, such as micropumps [31], micromixers [32], micro heat exchangers [33], catalyst supports [17], [33], and miniaturized analytical systems [34], [35], including a gas chromatograph on a silicon wafer [36]. However, systematic and extensive tests of such components in chemical applications were not performed, and straightforward development and fabrication processes for application-specific components and systems for chemical syntheses were lacking.

A new era began in 1995 with the first international workshop on microreaction technology [37], followed in 1997 by an international conference [38], which were initiated and organized by the Institute of Microtechnology Mainz (IMM) and the German Society for Chemical Apparatus, Chemical Engineering, and Biotechnology (DECHEMA) . The development was not only supported by research institutes [19], [21–25] but also by a group at DuPont and BASF [20], [39]. Since then research has begun in the chemical and pharmaceutical industries, and the first microreaction systems are being investigated for commercial applications [39], [40].

2. Fundamental Advantages of Microreactors

It is evident that miniaturization has a number of fundamental advantages in measurement and analysis devices. Miniaturization allows measurements to be performed with a device that needs less space, materials, and energy and often has a shorter response time. Miniaturized devices can be fabricated in parallel by batch processing at low cost and, in particular, a dramatic improvement of performance is achievable by integration of a multitude of miniaturized functional elements, as is well known in microelectronics.

In contrast to measurement systems, which produce information which is independent of the size of the system, reaction systems are designed to produce or convert materials or substances. When reaction systems are miniaturized, the production rate decreases and the value generated by the system per unit time becomes smaller. Therefore, it is usually assumed that the specific production costs increase with decreasing size of the production unit and plant, and it seems to make no sense to replace a large unit by a number of small units.

Nevertheless, in nature substances are always produced in an extremely small production unit, i.e., the living cell, which can be regarded as the most versatile chemical reactor to date. Its small size has been retained over long periods of evolution. To achieve high production rates, nature exploits the advantages of parallel units in the combined action of living cells in multicellular organisms. Besides this fundamental perception supporting the concept of microreaction technology, a variety of technological and commercial arguments have been presented [17], [20], [21], [27], [28], [41–44]. From a general technological viewpoint, the advantages of miniaturized reaction systems can be attributed to two fundamental properties: physical size and number of units.

For given difference in physical properties such as temperature, concentration, density, or pressure, the linear dimensions determine the gradients of these properties. With decreasing linear dimensions, the gradients, and hence the driving forces for heat transfer, mass transport, or diffusional flux per unit volume or unit area, increase. In addition, the surface area to volume ratio increases with decreasing linear dimensions, and therefore the effective exchange surface for mass and heat transfer. The volume of the system and its material holdup decrease with the third power of the linear dimension, and this, in combination with the higher effective exchange surface and gradients, results in shorter response times and should lead to simpler process control.

Because of the intensification of transport properties and the decreased holdup and response time, a variety of process conditions can be applied in microreactors which can not be realized in standard macroscopic devices. A typical example is the realization of nearly isothermal boundary conditions in a highly exothermic reaction by using the extreme heat-transfer rates of microreaction systems. Another example is the speed of mixing, which increases due to shortening of the diffusional path. As a result, the boundary conditions for a chemical reaction can be set over an extremely wide operating range and under favorably uniform conditions usually not achievable with standard laboratory equipment or production plants. Therefore, a major field of application of microreactors is process development to find optimum conditions for a production plant with regard to yield and selectivity [39], [40].

All of these characteristics that result from smaller physical dimensions remain largely unchanged when several miniaturized systems are operated in parallel to achieve the desired production rate. In addition, a larger number of systems results in a higher flexibility in adapting production rate to varying demand since, at least in principle, a certain number of systems may be switched off or further systems may be simply added to the production plant. A plant design based on a large number of small reaction systems can, again at least in principle, be modified to perform a variety of reactions by changing the manner in which the microreactor modules are interconnected. This flexibility may be supported by the considerably broader range of operating conditions of a microreactor compared to a macroscopic system.

Further advantages may result from cost reduction by mass production of modular microreaction systems. To obtain large production rates, many such modules must be assembled. However, there is also the alternative of retaining the

cost advantages of mass production but assembling smaller numbers of modules at various locations. Thus, a distributed production can be realized at tolerable costs, and storage and transport expenditure can be reduced, i.e., the modular approach of microreaction technology should facilitate production on demand and at the point of use.

Because of its small holdup and the flame-arrestor effect of its small channels, a single microreactor can be designed as a inherently safe apparatus. With a proper layout, this inherent safety should be maintainable in a large network of microreactors constituting a production plant. This safety advantage is further increased by the flexibility of distributed production and the short response time for control of a reaction unit. In addition, microreactor-based plants will be designed not with stirred tanks, which are one of the major reasons for operational disturbances, but with micromixing systems that have a negligibly small holdup. As a result, licensing problems might be eliminated, and a shorter time for transfer of laboratory results to production achievable. The possibility of encapsulating a small plant and of avoiding emissions is discussed in connection with small, microreactor-based production plants [41–43].

Major developments in microreaction technology have mainly been made in Europe and the United States [19–21], [23–25], [39]. Industrial and academic research groups are particularly active in Germany and the United Kingdom, but the other European countries are intensifying their development work [37], [38]. Current targets include reactions of explosive, flammable, or highly toxic components and processes with fast interruption of reactions by rapid cooling to suppress side reactions and give products of higher purity. Furthermore, due to advantageous geometries, large exchange rates at interfaces, e.g., in gas-phase catalysis, have been realized, yielding a high degree of conversion. Other developments concern the enhancement of mass transfer by using highly efficient micromixers, the generation of stable and uniform emulsions or dispersions, and the utilization of metastable intermediate species. These broad activities should widen the scope of chemical reactions and process regimes addressable for sustainable development and cost-effective production.

In spite of the scientific, technological, and commercial attractiveness of the microreactor concept in chemistry, it must be emphasized that this discipline is still in its infancy. Up to now, no microreactor process for chemical synthesis has been established commercially and no comprehensive theoretical basis or design rules exist for microchemical engineering. Therefore, this article on microreactors in chemistry should be regarded only as a snapshot of work in progress, which, however, may have a decisive impact in the future.

3. Microreactor Components

3.1. Micromixers

3.1.1. Injection of Multiple Microjets

A basic concept for a micromixer which was used as an integral part of a micro liquid dosing system was described in 1993 [32]. The central element of the mixer is a sievelike structure with a large number of regular holes (Fig. 1). During operation, the mixing area is filled with one liquid, and the other liquid is injected into the mixing volume through a multitude of microholes. Numerous microjets ("microplumes") are generated and increase the contact surface between the two liquids. The holes are positioned in rows 10 – 100 μm apart, which results in short diffusional paths between the jets. Typical flow rates are in the μL/s range, the hole diameter is some 10 μm, and the height of the mixing chamber some 100 μm.

The feasibility of the mixer concept was checked theoretically by numerical analysis of the diffusional flux. It was shown that mixing by injection of many microjets into a fluid stream is much faster than mixing with a large single-point injection (i.e., a flow configuration similar to a mixing tee). Multiple microjets give improved mixing for all flow rates; higher flow rates usually accelerate the mixing process.

Experimental studies included flow visualization for qualitative analysis of the mixing process. Microscopic observation of the jets showed that a homogeneous mixture was established within a few seconds. Absorption measurements were performed directly in the mixing area by using an optical fiber setup. Complete mixing at

Figure 1. Schematic of a micromixer with injection of multiple microjets into a mixing chamber [32]

a flow rate of about 1 μL/s was found within a mixing time of about 1 s.

3.1.2. Multiple Flow Splitting and Recombination

A micromixer designed by a research group at Danfoss and the Mikroelektronik Centret in Denmark has been used as an integral part of a micromachined chemical analysis system including an industrial chemical sensor [45]. It was operated in the flow range of 0.01 – 0.1 μL/s, which corresponds to a highly viscous flow with a Reynolds number less than 1.

The whole analysis system consists of a silicon/glass sandwich connected by anodic bonding. The mixing structure is shown schematically in Figure 2. One channel structure is etched into glass and the other into silicon. In the region where the channels overlap, they are separated by a structured plate defined by an etch-stop layer. The channel covered by the structured plate was generated by underetching in the [100] direction through slits in the plate. The maximum width of the channels is 300 μm and the depth is 30 μm. The width of the channels for the inlet branches of the micromixer units is about 150 μm. The thickness of the structured plate for separating the channels in the glass and the silicon wafer is 5 μm and the slit width 15 μm.

Figure 2. Mixing units of a static micromixer with multiple slit-shaped injection openings [45]

Mixing is performed by penetration of multiple slit-shaped flows into a main stream where the mixing mechanism is similar to that of the concept shown in Figure 1. However, several of the units shown in Figure 2 can be connected in series to improve the mixing quality. This can be of importance if the multiple slit-shaped streams of fluid 1 do not penetrate sufficiently deep into the stream of fluid 2 and contacting layers of the two fluids are formed.

The mixing process was observed by video microscopy, whereby the flow was visualized by of the color change in the reaction of phenol red with an acid. Zones with incomplete mixing

Figure 3. Scanning electron micrographs of a mixing element based on multilamination of thin fluid layers. The device consists of 2 × 15 interdigitated microchannels with corrugated walls, fabricated by LIGA technology [49]

were resolved near the slits. Complete mixing over the cross section of the outlet channel was obtained in 100 – 300 ms.

Micromachining with the Laser LIGA method has been used to fabricate similar devices with multiple flow splitting and recombination [5], [46]. Such mixing configurations have also been realized by wet-chemical anisotropic etching of monocrystalline silicon [47].

3.1.3. Multilamination of Fluid Layers

By means of the LIGA process micromixing devices with various characteristic dimensions have been fabricated which use the multilamination of flow with subsequent diffusional mixing [18], [26], [48], [49]. The design of such a LIGA micromixer is shown in Figure 3. The fluids to be mixed are introduced into the mixing element in counter-flow and stream into an interdigitated channels with corrugated walls. Typical channel widths are 25 or 40 µm. The channel configuration leads to a periodical arrangement of flow lamellae of the two fluids. The lamellar flow leaves the device perpendicular to the direction of the feed flows and, because of the thinness of the lamellae, fast mixing takes place by diffusion (see Fig. 4). The corrugated channel walls increase the contact surface of the lamellar streams and improve the mechanical stability of the separating walls.

Figure 4. Multilamination of streams in channels with corrugated walls, leading to fast mixing by diffusion [48]

The optimum operating conditions of such a device depend on the height and the length of the channels and the properties of the fluids such as viscosity, flow rate, and pressure. The flow and mixing conditions can be adjusted by withdrawing the fluid through a slit which forces interpenetration across a defined contact zone.

Figure 5 shows the assembly of the micromixer. The LIGA device is inserted into the bottom part and covered with a top part which contains the two inlets for the feed streams and the outlet for the mixture. The discharge slit is also integrated in the top part. A wide variety of materials, including plastics, metals, metal alloys, and ceramics, are suitable for the fabrication of interdigitated structures by the LIGA process and its variants. There is practically no restriction concerning the materials of the top and bottom parts. For commercial devices various metals (e.g., nickel and silver) have been favorably applied. The top and bottom parts are

Figure 5. Micromixer consisting of a LIGA device with an interdigitated channel structure and top and bottom parts (Source: IMM [48], [49])

usually made of high-alloy stainless steel and in some cases of plastics.

Micromixing systems of the type shown in Figures 3 and 5 have been tested extensively with miscible fluids. The mixing quality was determined [48] by using feed fluids which react after mixing via two different pathways, a fast one and an ultrafast one, to give differently colored products. In this case the fast reaction gives a colored product, while the result of the ultrafast reaction, which dominates at ultrafast mixing, is a colorless solution. The measurements showed that complete mixing is obtained a few millimeters downstream of the contact zone of the lamellar flows, which corresponds to a mixing time of some 10 ms. The flow rate in these experiments ranged from 10 to 1000 µL/s, and the pressure losses were between 10 and 1000 mbar. For qualitative comparison, the same feed fluids were mixed by using a mixing tee with equal sizes of feed and outlet channels and in a strongly stirred mixing vessel. Such standard devices could not compete with the mixing speed of the LIGA micromixer.

Figure 6. Flowing dispersion of argon bubbles in an aqueous solution generated by means of a LIGA micromixer [50]

Particularly interesting is the utilization of LIGA micromixing systems for generating gas/liquid dispersions [50] and emulsions [51]. Typical results are shown in Figures 6 and 7. Extremely narrow distributions of gas bubbles in liquids and of droplets of one liquid in another can be obtained. These narrow distributions are limited to certain boundary conditions and compositions. The model silicon oil/water emulsion (Fig. 7) was generated without any standard emulgator. Some such emulsions generated by the LIGA micromixer proved to be stable for several months.

Other types of mixing devices using the principle of flow multilamination with subsequent diffusional mixing have been described. Their microstructures differ from the interdigitated channel configurations. Mixers comprising stacked platelets with hundreds of parallel microchannels and a mixing chamber were realized at the Karlsruhe Nuclear Research Centre [52]. Industrial tests were conducted to evaluate their performance in chemical reactions

The two fluids to be mixed are guided in adjacent platelets, which are fed from separate fluid reservoirs. The orientation of the microchannels between reservoirs and mixing chamber is either straight or curved. Thus, an alternating arrangement of fluid layers with a thickness of about 100 µm is generated. Mixing is performed by diffusion between these thin layers within the mixing chamber. The platelets were fabricated by mechanical surface shaping of metal tapes [10]. Various mixers with platelets made of stainless steel, Hastelloy, and palladium were realized.

Figure 7. Emulsion of silicon oil droplets in water generated by means of a LIGA micromixer. The emulsion contains no standard emulgator [51].

3.2. Micro Heat Exchangers

To effectively transfer heat from one flowing fluid across a solid boundary to another flowing fluid, sufficiently large contact areas and temperature gradients are required. Another important criterion is the ratio of heat transfer to pressure loss. This is particularly favorable in compact heat exchangers in which the fluid stream is split into many partial streams of small dimensions (e.g., plate heat exchangers). These partial streams are characterized by correspondingly low Reynolds numbers, i.e., they show viscous rather than turbulent behavior. Decreasing the dimensions of the fluid flow increases the temperature gradients and the exchange surface to volume ratio, that is, miniaturization leads to a better heat exchange. The decreased flow dimensions are inevitably associated with increased viscous losses, but the overall heat transfer to pressure loss ratio is improved.

3.2.1. Cross-Flow Heat Exchange in Stacked Plate Devices

This basic concept of performance improvement through miniaturization was demonstrated at the Karlsruhe Nuclear Research Centre, where the development of cross-flow micro heat exchangers was started in the 1980s [10], [11], [53]. A typical cross-flow micro heat exchanger is shown in Figure 8. About 100 platelets, several square centimeters in size and containing rectangular microchannels, are stacked crosswise and bonded hermetically. In this way, two separate passages for the heat transfer fluid and the process fluid with about 4000 microchannels are formed. The cross section of a single microchannel is $100 \times 80\,\mu m$, the material thickness between the two fluids in the crossing channels is $20-25\,\mu m$. The stack is fitted with top and cover plates and connected to fittings for the inlet and outlet ducts of the heat exchanger fluids.

The active volume of such a micro heat exchanger is typically $1\,cm^3$ with an inner surface area of $300\,cm^2$ and a heat transfer surface of $150\,cm^2$. The passages are helium-tight both with respect to each other and to the outside. Because of the small dimensions of the channels and the strong bonding, a relatively high operating pressure can be applied. Such devices have

Figure 8. Central component of a cross-flow micro heat exchanger consisting of a stack of crosswise oriented metal platelets (source: Forschungszentrum Karlsruhe)

been tested at pressures up to 25 bar, but this is presumably not the upper limit. Micro heat exchangers have been made from various materials, including aluminum alloys, copper, silver, titanium, and stainless steel. The geometry of the channels, the number of stacked platelets, and the construction of the macroscopic fluid connectors can be adapted to a wide variety of applications [33], [54].

Figure 9. Micro heat exchanger with connections for fluid supply (source: Forschungszentrum Karlsruhe)

Figure 10. Influence of the hydraulic diameter of the microchannels on the performance of a cross-flow micro heat exchanger, shown by the dependence of heat transfer rate on water mass flow (source: Forschungszentrum Karlsruhe)

Microfabrication of the channels in the platelets is performed by mechanical surface shaping of metal tapes [10]. When aluminum alloys and copper are used, parallel grooves are cut into the tape by ground monocrystalline diamonds. Since iron alloys are incompatible with diamonds, surface shaping of stainless steel is performed with ceramic microtools, but these inevitably result in larger tolerances. With titanium the best results are achieved with polycrystalline diamond tools.

After the grooves have been cut, the tape is cut into platelets of the desired dimensions, which are stacked crosswise to form a cube. The platelets are bonded together by diffusion bonding, and the cube is connected to the macroscopic fittings by electron-beam welding (Fig. 9).

In Figure 10 the measured thermal power (heat transfer rate) is plotted versus the mass flow rate of water per passage for three micro heat exchangers with different hydraulic diameters of the microchannels [52]. The heat transfer rate increases with decreasing hydraulic diameter of the channels. However, since the decreased hydraulic diameter also results in higher pressure losses for a given mass flow and channel length, the ratio of heat transfer to pressure loss is the fundamental performance criterion.

From the results shown in Figure 10 the heat transfer coefficients were calculated (Fig. 11) [52]. Even at the maximum flow rate, laminar flow conditions should exist in each single microchannel. The overall heat transfer coefficients achievable with the micro heat exchanger reach values of more than $20\,\mathrm{kW\,m^{-2}\,K^{-1}}$, which considerably exceed those of macroscopic devices.

Figure 11. Overall heat transfer coefficients versus mass flow for three heat exchangers with microchannels of various hydraulic diameter (source: Forschungszentrum Karlsruhe)

At a mean temperature difference of 59.3 K, a power of 19.2 kW was transferred in an active volume of $1\,\mathrm{cm^3}$. The overall heat transfer coefficients were up to $25\,\mathrm{kW\,m^{-2}\,K^{-1}}$, corresponding to a volumetric heat transfer coefficient of $0.3\,\mathrm{kW\,cm^{-3}\,K^{-1}}$.

Micro heat exchangers with an active volume of $27\,\mathrm{cm^3}$ and a power of up to 200 kW are now available [52], [55].

3.2.2. Counterflow Heat Exchange in Stacked Plate Devices

The LIGA process can be used to manufacture three-dimensional microstructures of nearly any cross-sectional shape from a wide variety of materials. This flexibility allows counterflow micro heat exchangers to be fabricated with extremely high precision, including inlet and outlet ducts ands other auxiliary structures. Compared to other heat exchange configurations, counterflow is the most efficient from a thermodynamic point of view. The principle of such a micro heat exchanger module is shown in Figure 12 [18], [49]. It consists of platelets with an outer frame and an inner thin membrane, stacked to form a plate-type heat exchanger. The membranes have parallel fins that form channels that guide the fluids and increase the mechanical stability of the device, which is of major importance for operation at high differential pressure. The platelets comprise openings in their corners, where two diagonal openings alternately form the inlet and outlet ducts for one fluid. The other fluid passes through the remaining openings to the adjacent platelet. On both sides of the membranes, which are very thin to ensure efficient heat transfer, uniform countercurrent flow is established by the parallel fins. The total amount of heat transferred in such a stacked device is determined by the number of platelets, which is limited by the pressure losses in the inlet and outlet channels.

A prototype of a micro heat exchanger based on the above principle is shown in Figure 13. It consists of stacked platelets clamped between a top and bottom part made of a high-temperature polyether ether ketone (PEEK) engineering plastic. The top part contains the inlet and outlet ducts for the two fluids. The platelets are 20×20 mm square copper foils with a thickness of 20 to 500 μm. The foils are equipped in their center area with 37 nickel fins with a width of 30 μm and a height of some 100 μm, which form fluid channels with a width of 300 μm. The heat transfer area is to 140 mm^2 per platelet. Each foil is tightly connected to a nickel frame whose thickness corresponds to the height of the fins. The frame also includes the openings of the fluid ducts and alignment structures.

The platelets of the micro heat exchanger shown in Figure 13 were made by the LIGA process, i.e., deep lithography and subsequent electroforming. In the first step, the complementary pattern of the fins and the frame is generated by X-ray lithography in a thick resist layer deposited on an electrically conducting substrate, usually titanium. In the second step, nickel is electrodeposited into the gaps of the lithographic structure to form the fins and the frame. Then, a thin copper film is sputtered onto the resist layer, the fins, and the frame. A thick copper coating is grown on the sputtered copper film by electrodeposition. The final thickness of the copper foil is adjusted by mechanical posttreatment. The duct openings are made by drilling.

Since the above fabrication method is not suitable for mass production, a cheap replication method was developed. It starts with a platelet of a micro heat exchanger manufactured by deep lithography and electroforming as described above. The platelet is then used as an electrode to transfer its complementary structure into a hard metal by micro electro discharge machining (LIGA-μ-EDM). In this way, a precise tool of high mechanical stability is obtained which allows cheap mass production of platelets by embossing. Promising results have been obtained with relatively soft materials like aluminum. This embossing process is being extended to stainless steel and other materials. Powder injection molding (PIM), punching, and wet etching are also under development for cost-effective and application-specific mass fabrication of micro heat exchangers and other components of microreactors.

The performance of the counterflow micro heat exchanger was demonstrated in preliminary measurements of heat transfer between streams of cold (20 °C) and hot (75 °C) water. Measurements of heat transfer rates as function of volume flow rate were performed on four-layer stacks of two types of platelets: one with a 450 μm thick fluid layer, and the other with a fluid layer thickness of 100 μm (Fig. 14).

The heat transfer rate increases with decreasing thickness of the fluid layer. The dependence of the heat transfer coefficient on the volume flow rate, calculated from the data in Figure 14 is shown in Figure 15. The heat transfer coefficients achieved in these preliminary measurements considerably exceed those of conventional heat exchangers.

3.3. Microchannel Catalyst Structures

Catalysts are incorporated in microreactors as microstructures consisting of bulk catalytic material by wet impregnation of nanoporous supports, physical vapor deposition (PVD), chemical vapor deposition (CVD) of catalytic thin films on microstructured surfaces, and by packing of channels or other microstructures with fine-grained catalytically active powder. The cross-flow micro heat exchanger described in Section 3.2.1 was also used to perform catalytic gas-phase reactions (see Sections 3.2.1 and 3.2.2) [52]. The materials for the channeled platelets included aluminum, copper, silver, and stainless steel. In the case of aluminum platelets, anodic oxidation was used to create an oxide layer with a regular pore structure in which palladium was embedded as a catalytically active material [29], [56–58]. Copper platelets with surface oxidation [24], [30] and silver platelets [28], [40] served as bulk catalysts. For high-temperature applications, platinum ribbons were used with microholes generated by micro electro discharge machining [19]. To investigate controlled catalytic combustion of explosive gas mixtures, stainless steel platelets with channels were covered with Al_2O_3 by CVD, and platinum was applied as catalytically active material by wet impregnation [59].

3.3.1. Partial Oxidation of Propene to Acrolein

One of the first reactions investigated in the flow-through configuration in stacked platelets with microchannels was the heterogeneously catalyzed partial oxidation of propene to acrolein.

The microchannel reactor used for these experiments, which was developed at the Forschungszentrum Karlsruhe, consisted of copper with a catalytically active surface of Cu_2O [24], [30]. Typical reaction conditions are a temperature of 350 – 375 °C and concentrations of propene and oxygen of less than 1 vol % in nitrogen as carrier gas. The propene conversion rate and the selectivity changed considerably during long-term operation of the reactor, and this is attributed to a change in the composition of the catalytically active layer. Using bromomethane ($c = 2.25$ ppm) as a promoter to stabilize the metal oxide layer gave an increase in selectivity and a slight decrease in conversion.

3.3.2. Selective Partial Hydrogenation of a Cyclic Triene

Compared to macroscopic systems, microchannel devices have a much larger surface area to volume ratio. However, microchannel devices never reach the values of the nanoporous structures typical of many catalysts and catalyst supports. The relatively low conversion rate in the partial oxidation of propene to acrolein (see Section 3.3.1) was attributed to the small catalytic surface area of the microchannels consisting of nonporous cuprous oxide.

Therefore, a method was developed for the generation of a highly porous surface on the platelets and microchannels. The surface of microstructured aluminum platelets was modified by anodic oxidation in aqueous oxalic acid to give a thin layer of Al_2O_3 with a regular structure of pores, the depth of which can be adjusted by means of the operating conditions of the electrochemical process. This porous nanostructure served as a support in which catalytically active components could be embedded [24]. Figure 16 shows a schematic of the channel microstructure and the oxide nanostructure. The distribution of the pore diameters, which are in the range of some tens of nanometers, is highly uniform, a fact which long been utilized for the colorization of anodized aluminum and for the production of isoporous alumina filtration membranes. The surface area to volume ratio is thus increased by a factor of 10^4 to 10^5, and values comparable to those of fixed-bed catalysts are attainable. However, the regular distribution of pores of almost equal size and depth is a clear advantage of the microreactor compared to standard catalyst beds.

The performance of this microreactor was tested in the stepwise hydrogenation of *cis*,*trans*,*trans*-1,5,9-cyclododecatriene to the partially hydrogenated, thermodynamically unstable intermediate cyclododecene (CDE) with the aim of achieving as high a yield as possible (Fig. 17) [29], [55], [56], [57]. For comparison, other catalysts such as conventionally coated granules, pieces of activated aluminum wire, and pieces of activated aluminum foil were used. Palladium was applied as catalyst.

Figure 18. Yield and conversion enhancement by highly ordered catalyst configuration and flow conditions. The microchannel reactor achieves much better values than a catalyst bed with coated granules; partially ordered configurations give intermediate values (CAT A: pore depth 240 µm, commercial industrial palladium catalyst; CAT B1, B2, C: pore depth 37 µm, wet impregnation of anodic oxidized aluminum with palladium acetyl acetonate precursor) [29], [55]

The microchannel reactor proved to have clear advantages. Compared to standard devices

Figure 19. Reactor configurations for gas-phase synthesis of aldehydes by oxidative dehydrogenation of alcohols [44]

with conventionally coated granules it gave a 25 % higher yield of CDE. This was attributed to the regular pore system with defined and relatively short depths of the pores, the uniform distribution of the catalytically active component in the pores, and the uniform flow conditions in the microchannels. Structures which are more regular than coated granules such as pieces of activated aluminum wire or foil gave results closer to those of the microreactor (Fig. 18).

3.3.3. Oxidative Dehydrogenation of Alcohols

Aldehydes are mostly produced by oxidative dehydrogenation of alcohols. About 100 years ago a gas-phase process for the production of formaldehyde on a silver catalyst was developed at BASF to produce formaldehyde (R = H) [40], [44].

Almost quantitative conversion with a selectivity of 95 % was achieved on a small scale on a large scale in a reactor of diameter 7 m.

Researchers at BASF tried to establish a similar process for the synthesis of derivatized aldehydes. In a small-scale pan-shaped reactor (diameter 5 cm) a selectivity of 90 % at 50 % conversion was achieved, but the selectivity dropped to 45 % when the reactor diameter was increased to 3 m. Therefore, this process was regarded as technically infeasible.

It turned out that optimum conditions are attained in an isothermal process with a short residence time. This explains the unsuitability of multitubular reactors with a tube length of several meters, which allows isothermal operation but has a long residence time. Considerable improvements were obtained with a short multitubular reactor (tube length ca. 10 cm; see Fig. 19).

By means of a microchannel reactor, developed at the Forschungszentrum Karlsruhe [28], a cross-flow heat exchanger design (see Section 3.2.1) comprising silver platelets with 200 microchannels (cross section $320 \times 400\,\mu m$) a further improvement was obtained. Due to the excellent heat-transfer performance and the small dimensions, isothermal operation is combined with short residence time. The residence time is an order of magnitude lower and the heat-transfer coefficient an order of magnitude higher compared to the short multitubular reactor.

In Figure 20 the selectivity of the oxidative dehydrogenation is shown as a function of the conversion. The short multitubular reactor which was optimized over a period of several years reaches a selectivity of 85 % at a conversion of 50 %. At even higher conversions selectivities of up to 96 % were achieved with the microchannel reactor. This is a promising result, also from a commercial point of view, since the reactants are utilized more effectively and a decrease of the amount of sideproducts will lower

the expenditure for subsequent separation and purification.

BASF researchers emphasize that such developments could not have been achieved by using conventional laboratory techniques, but were only feasible by means of microreactors. They expect a significant reduction of development periods and considerable process improvements by using microreactors as a versatile development tool for optimizing production-scale syntheses.

3.3.4. Gas-Phase Synthesis at High Temperature

In a multilateral industrial project dealing with the production of the hazardous gas hydrogen cyanide by oxidative dehydrogenation of methane and ammonia, researchers at IMM developed a multichannel catalyst device [19]. Uniform heat distribution to realize an isothermal process was again one of the major objectives.

Figure 20. Comparison of the performance in aldehyde synthesis for a microchannel reactor and a short multitubular reactor [40]

The multichannel catalyst device consists of a platinum microstructure embedded in a ceramic support (Fig. 21). The platinum microstructure has parallel microchannels with approximate dimensions of some ten micrometers in diameter and with a length of some hundred micrometers. It can be heated electrically to 1500 K. Structuring of the platinum was performed by micro electro discharge machining, including wire spark erosion and die sinking. The ceramic support was manufactured by precision machining and casting.

Figure 22 shows the catalyst structure glowing in air. The thermal insulation of the hot catalyst structure by the ceramic support is so efficient that the outer border of the ceramic support can be kept close to room temperature.

First experiments prove the feasibility of this catalyst concept for high-temperature reactions. Significant amounts of hydrogen cyanide were measured corresponding to a yield of 32 %, which is about half the value of the industrial process. The conversion of methane is nearly quantitative, however, the selectivity to hydrogen cyanide still has to be improved.

3.4. Microseparators

A number of current investigations in microreaction technology deal with miniaturized separation devices using extraction, filtration, and diffusion processes. The fabrication methods and materials for such devices are described in the preceding chapters and are not discussed in detail here. There are many publications concerning electrophoretic and chromatographic separation devices and miniaturized distillation apparatus. Since these devices are mostly regarded as components of analytical systems, they are not described in this chapter. The reader is referred to [34].

3.4.1. Exchange between Immiscible Fluids

Extraction processes considered here are based on the contact of two immiscible fluids and solute transfer between the two phases. Since miniaturization leads to an increase of surface area to volume ratio, it results in a corresponding enlargement of the exchange interface; hence, intensification of the process by miniaturization should be possible.

A configuration applicable at small dimensions consists of partially overlapping microchannels, which facilitates a largely undisturbed flow of the two phases in their channels and solute exchange between the nondispersed fluids (Fig. 23) [60], [61]. In principle, cocurrent flow, countercurrent flow, cross-flow and other

Figure 21. Multichannel device consisting of a platinum catalyst structure (left) and central part of ceramic support made of aluminum oxide (right) [19]

Figure 22. Glowing catalyst structure in air [19]

Figure 23. Schematic of solute exchange between immiscible fluids in partially overlapping microchannels (left) and scanning electron micrograph of the cross section of the partially overlapping microchannels (right) [60]

configurations can be realized. Adjustable devices with partially overlapping channels allow the exchange area to be adjusted to the operating conditions.

Further investigations deal with the stability of parallel contacting streams of two immiscible liquid phases which, after solute transfer, are split at the end of the contact zone by wedge-shaped flow divider [62], [63]. Stable flow can be achieved within a certain range of flow rates and viscosities. The stability of the flow is influenced in particular by surface forces, whereas other parameters such as buoyancy, momentum, and viscous stresses are of minor importance. Splitting of the contacting fluids by a wedge-shaped flow divider can be performed with high precision and only minor mixing of the two phases.

Other microextraction units use sieve-like structures to separate the two nondispersed phases [64]. This can be a perforated sheet or channels similar to the device shown in Figure 1. A variant of this type of extraction units has adjacent channels for the two fluids with slits for exchange between the two phases (Fig. 24). In a counterflow device the pressure drop in contacting channels is in the opposite direction and, as a result, a bursting of the fluid from one channel into the adjacent channel may occur. Such a bursting can be avoided by proper adjustment of the slit width.

Figure 24. Scanning electron micrograph (left) and schematic (right) of an extraction unit with adjacent channels for two fluids with slits, oblique to the flow direction, for exchange between the two phases [51]

A very effective means for extraction with dispersed phases may be emulsification in micromixers (see Section 3.1.3). Because of the small size of the droplets and the narrow size distribution, a large exchange surface and a sufficient stability may be obtained [51]. Such devices may become of major importance for separation processes based on the mixer/settler principle.

Figure 25. Scanning electron micrograph of a cross-flow filter consisting of lamellae arranged at an angle of attack to the flow direction [65]

3.4.2. Filtration, Diffusion, and Aerodynamic Separation

In the macroscopic range, filtration and sieve structures are often carefully designed with regard to the shape and position of the openings. In the microscopic range usually porous materials with irregular pattern are applied. Microfabrication methods allow the production of completely isoporous microfilters from a wide variety of materials, whereby the size, shape, and position of each pore can be designed. Typical microfilters have pore dimensions in the micrometer range. Special configurations allow the realization of cross-flow filters for concentrating suspended particles or cells. Such cross-flow filters consist of lamellae arranged at an appropriate angle of attack to the flow direction, resulting in a configuration similar to a Venetian blind (Fig. 25) [65].

In the case of membrane units, microfabricated devices are useful as carrier structures with integrated inlets and outlets for fluids. Integrated membrane units are being developed for gas-phase microreactors [66], and microfabricated carrier structures could become important in fuel cells.

At the Karlsruhe Nuclear Research Centre aerodynamic separation systems were developed for the enrichment of the light uranium isotope ^{235}U by means of miniaturized curved nozzles [67]. Analogous to a gas centrifuge, the driving force for the separation of molecules with different masses is the pressure diffusion effect. In spite of a very large development expenditure, the commercial implementation of this so-called separation nozzle method failed, but the LIGA process [3] and the mechanical microfabrication process [27] developed in connection with this method have since become powerful tools for producing a wide variety of microreactor components.

4. Microreaction Systems

4.1. Synthesis of Hazardous Gases in Microfabricated Silicon Devices

DuPont has described the performance of a number of reactions (Table 1) in microfabricated silicon devices [20]. This pioneering development work included detailed analysis of the advantages and applications of microreactors. The devices were not described in detail, but the major components, operations, and the reactions performed have been listed. A modular approach was used to adapt microreaction systems to a variety of reactions, mainly catalytic and noncatalytic gas-phase reactions of hazardous substances. The DuPont microreactor system is based on a stacked silicon wafer architecture consisting of, for example, a static mixer and a reaction chamber for rapid mixing and short contact times. Another type of a microreactor is equipped with a reaction chamber with a "window" for photocatalysis at a specific wavelength.

The formation of the hazardous compound methyl isocyanate has been described in detail. It is synthesized by an exothermic process at high temperatures.

$$[\text{Reactant}]_{\text{Hexane}} + \text{conc. } H_2SO_4 \longrightarrow \text{Byproduct 1}$$

$$\downarrow$$

$$[\text{Intermediate}]_{H_2SO_4} \longrightarrow \text{Byproduct 2}$$

$$\downarrow$$

$$[\text{Product}]_{H_2SO_4} \longrightarrow \text{Byproduct 3}$$

The reaction was run in a microreactor consisting of three etched silicon wafers with a microreactor pattern and two capping wafers (Fig. 26). The reactants were mixed before entering the microfabricated heat exchanger channel packed with polycrystalline silver particles. The product stream was analyzed by capillary gas chromatography.

The experiments successfully demonstrated the feasibility of a microreactor for processing hazardous substances. The conversions for isocyanate formation were in the range of 85 – 95 % for feed conditions and flow rates corresponding to those of a standard laboratory-scale reactor. However, the selectivity did not reach the standard values. The absence of corrosion or material-compatibility problems in the experiments may result from passivation of silicon by oxygen.

Table 1. Selected reactions tested in microfabricated silicon devices [20]

Reactants	Main products	Reaction category
Cyclohexylamine, phosgene	cyclohexyl isocyanate	high temperature, hazardous
Butylamine, phosgene	butyl isocyanate	high temperature, hazardous
Hydrogen chloride, oxygen	chlorine, water	catalytic, hazardous
Carbon monoxide, chlorine	phosgene	catalytic, hazardous
Methylformamide, oxygen	methyl isocyanate	catalytic, high temperature, hazardous
Methane, ammonia	hydrogen cyanide	catalytic, high temperature, hazardous
Dichloromethylsilane, chlorine	trichloromethylsilane, hydrogen chloride	photochemical, hazardous

Figure 26. Exploded view of the DuPont microreaction system composed of silicon wafers [20]

Temperature profiles were measured along the catalyst bed and showed a maximum and indicated some heat losses. In spite of the relatively high thermal conductivity of silicon, the high rate of heat generation resulted in a catalyst temperature of up to 300 °C. In contrast to a microreaction system used for a highly exothermic liquid-phase reaction (see Section 4.5 [39], [40]), isothermal operating conditions were not achieved in the DuPont reactor, i.e., the reaction

conditions were between isothermal and adiabatic.

The experiments on the formation of methyl isocyanate in the microreactor clearly demonstrated that microreaction technology is a promising approach for production of hazardous chemicals at the point of use. Although the number of production units increases when a large plant is replaced by distributed microreaction facilities, risks due to transport and storage are eliminated and a smaller total holdup may be realized. Together with the inherent quenching of explosions in microchannels, this should result in a net improvement of safety.

More recent experimental results have demonstrated that more favorable boundary conditions for chemical reactions can be achieved in microreactors compared to macroscopic devices. This may be an increase in selectivity and yield by applying isothermal conditions [39] , [40] or accelerated conversion by using higher temperatures.

4.2. Partial Oxidation of Methane in a Stacked Stainless Steel Sheet System

At the Pacific Northwest National Laboratory (PNNL) of Battelle Institute a microchannel reactor was developed for the oxidation of methane with air yielding synthesis gas (CO, H_2) in a fast exothermic reaction [68].

$$CH_4 + 1/2\,O_2 \rightarrow CO + 2\,H_2$$

This reaction is of interest for generating hydrogen for fuel cells with proton exchange membranes. These fuel cells have a number of advantages compared to high-temperature fuel cells which use ceramic membranes for oxygen ion transport and can be operated with methane.

The hydrogen yield in the partial oxidation of methane is decreased by hot spots in the reaction volume [68]. In addition, thermal runaway effects result in further undesired conversion of the products carbon monoxide and hydrogen. These phenomena can be avoided, in principle, by microreactor systems, which allow isothermal processing and extremely short contact times in the millisecond range. Because of the excellent conditions for heat removal from the exothermic reaction, microreactors should also allow operation at a much higher conversion than macroscopic devices, which usually require dilution with inert gas. In addition, inherent safety may be guaranteed since the small channels and reaction volumes can act like integrated flame arrestors and quench explosions. An excellent catalyst for partial oxidation of methane is rhodium, which inhibits undesired coke formation and hydrogen oxidation because of the high activation energy barrier of rhodium surfaces.

Figure 27. Stainless steel reaction plate [68]

The researchers at PNNL have developed a microreactor for partial oxidation of methane with a planar-sheet architecture. It consists of stacked stainless steel plates, which include combustion, reaction, preheating, quenching, spacer, and top and bottom plates. In the process sequence, the combustion of a fuel is used to heat the reaction volume by means of a gas heat exchanger, and the remaining heat is used for preheating the reactants in a further heat exchanger. The reaction products (H_2, CO) are quenched against air in a third heat exchanger

A schematic of the reaction plate is shown in Figure 27. It has dimensions of $7 \times 3.8 \times 0.4$ cm and contains 37 parallel channels with a depth of 1500 μm and a width of 254 μm separated by fins with a width of 254 μm. The header or the channels over a quarter of their total length are filled with a rhodium-impregnated silica powder. The stainless steel plates are manufactured by preci-

sion engineering or electro discharge machining (EDM). Thin nickel foils are used for sealing the stacked plates.

Extensive tests were performed on the stacked plate microreactor system with a gas chromatograph for analyzing the reaction products. Because of leakage problems the desired operating temperature of 900 °C could not be reached, and the experiments were limited to 700 °C. The inlet feed rate was about 100 $sccm^3$ (standard cubiccentimeter, cm^3 at RT and atmospheric pressure) resulting in a residence time of about 50 ms.

The selectivity and conversion were measured over the temperature range of 300 to 700 °C (channels filled with catalyst) and 300 to 600 °C (header filled with catalyst) and compared to the equilibrium values (Fig. 28). The measured and the equilibrium values differed strongly, as expected for the nonequilibrium process conditions of the experiments. Practically no coke formation was observed, and the concentrations of combustion products (CO_2 and H_2O) were below the equilibrium values. When the front section of the channels was filled with the catalyst, the selectivity for carbon monoxide formation increased with increasing temperature and, in contrast to hydrogen selectivity, exceeded the equilibrium values. When the header was filled with the catalyst, nearly constant selectivities for carbon monoxide and hydrogen over the whole temperature range between 300 and 600 °C were found. This was attributed to much higher local temperatures.

Evidently, the measurements do not cover all aspects of partial oxidation of methane in microreactors, in particular with respect to the local temperature distribution in the reaction zone due to insufficient heat transfer. Nevertheless, these results should be regarded as a first step in the utilization of microreactors in the generation of synthesis gas.

4.3. Synthesis of Ethylene Oxide in a System with Integrated Mixing and Catalyst Structures

On an industrial-scale ethylene oxide is produced with silver catalysts on aluminum oxide having pore sizes of 0.5 – 50 µm at 250 – 300 °C. This reaction is perfectly suited for demonstrating the advantages of microreaction technology. The optimum operating conditions of macroscopic devices and the reaction kinetics are well known, and it is a gas-phase process with a moderate reaction velocity. Ethylene oxide is a volatile toxic substance for which the utilization of microreactors could eventually result in safety advantages. Therefore, a project team including seven research institutes and an advising committee with members from four chemical companies was established to analyze the potential advantages of microreaction systems in this field [19], [69]. The task list of the project team comprises the realization of the microreaction system, including components for mixing, catalysis, gas separation, and analysis, as well as extensive process simulation.

Figure 29 shows the disassembled components for mixing and catalytic reaction of the microreaction system. It was designed and constructed for use under reaction conditions similar to those applied on an industrial scale, i.e., for temperatures up to 300 °C and pressures up to 25 bar. The system comprises stacks of microstructured layers for mixing and catalytic reaction which are inserted in a stainless steel housing. In the process sequence, the reactants ethylene and oxygen are introduced from opposite sides into a static micromixer which feeds a diffusion volume and a subsequent catalyst zone.

The microstructured components for mixing and catalysis were manufactured by a combination of photoablation with excimer laser radiation and electroforming (Laser-LIGA) and by micromilling. The reactor housing was fabricated by conventional milling techniques in combination with micro electro discharge machining and welding [19], [69].

The static micromixer consists of stacked nickel platelets coated with gold to prevent catalytic activity. The platelets have circular concentric channels (Fig. 30, and the inlets to the channels of a platelet are alternately connected to the ethylene and oxygen sides. The thickness of the platelets is 200 µm, and the depth of the channels 50 µm. To obtain equal flow rates and resistances for all channels, the variation in the channel cross sections was determined by a fluidic simulation. The reactants are mixed by multi-entrance feeding into a diffusion volume with a contact length of 1 mm.

Figure 28. Selectivity for methane partial oxidation: experimental versus equilibrium [68]

Figure 29. Disassembled microreaction system for ethylene oxide synthesis with housing, fluid connectors, and platelets for stacking catalyst and mixing structures [19]

The catalyst zone following the diffusion volume comprises a stack of solid silver platelets with parallel straight microchannels (Fig. 31).

The channels have a width of 400 µm and a depth of 50 µm to realize short diffusion paths to the catalytic surface. By means of extensive computer simulation it was shown that, even without a heat exchanger, a hot spot of less than 1 K can be achieved and, accordingly, nearly isothermal process conditions for ethylene oxidation exist.

It was found, that the selectivity in the microreactor increases with increasing partial pressure of oxygen. Although characterization of the microreactor is not yet finished, experiments revealed that the performance of the microreactor is close to that of industrial-scale reactors. Without using any chlorine compounds as oxidation inhibitors, a selectivity of 65 % for a conversion of 6 % and a reaction rate of $7 \times 10^{-5}\,\mathrm{mol^{-1}\,m^{-2}}$ has been observed at 350 K and 5 bar, i.e., at low pressure in comparison to the industrial process.

Figure 31. Photograph of silver catalyst platelets with parallel shallow channels (left) and scanning electron micrograph of stacked platelets forming a multichannel catalyst zone [19]

4.4. Oxidation of Ammonia in a Thin Film Silicon Device with Integrated Catalyst, Heaters, and Sensors

The future development of microreactor systems will be based more and more on detailed simulation of the process that takes into account the geometrical boundary conditions of the flow system, as well as thermal, concentration, kinetic, and other data. To provide experimental data and a suitable simulation strategy, a joint research team of MIT and DuPont studied ammonia oxidation in a microreactor. This reaction is particularly suited for such a study because it is highly exothermic and very sensitive to operating conditions such as temperature and composition and cooling or heating effects. It allows an investigation of the ignition and extinction phenomena characteristic of partial oxidation reactions and rapid quenching of reactions.

The simulation was based on a finite-element method and includes a simultaneous solution of momentum, energy, and mass conservation. The geometric boundary conditions were taken fully into account and incorporated three-dimensional simulation, the transport properties in the gaseous mixture, and the kinetic data of the reaction.

Two microreactors were made by means of standard silicon micromachining which mainly differ in their heat removal characteristics [25], [70], [71]. Both types comprise a simple T-shaped channel for introducing the reactants in a counterflow configuration and a longer straight reaction channel (Fig. 32). The T-shaped channel, which has a width and a depth of about 500 µm was etched into a silicon platelet with a size of 15 mm × 25 mm. The bottom of the channel structure was sealed with an aluminum plate with openings for the reactants and the reaction products. The reactants enter at the two inlets of the T-shaped channels and mix at the entrance of the reaction channel. The reaction products leave at the base of the T through the outlet opening in the aluminum plate and are analyzed by a mass spectrometer. On the side oppo-

site to the aluminum plate, the T-shaped channel is covered with a thin membrane which serves as a substrate for deposition of a platinum catalyst layer as well as heaters, temperature sensors, and thermal flow sensors by standard methods of thin-film technology.

In the first reactor type the membrane is made of silicon nitride and has a thickness of 1 µm. Because of the low thermal conductivity of silicon nitride and the small thickness of the membrane, heat generated, e.g., by ignition on the catalyst surface or by the heaters, is removed poorly. The second reactor type has a 2.6 µm silicon membrane which, because of its higher thickness and the much higher thermal conductivity of silicon, removes heat generated near the membrane much more efficiently.

In extensive investigations temperatures were determined as a function of channel width, channel length, time, heater power input, etc. Good agreement between measurements and simulated temperature profiles was obtained for pure oxygen as a nonreacting gas and for the reacting oxygen/ammonia mixture.

An interesting result was due to the different heat dissipation behavior of the two reactors and membranes (Fig. 33). In the silicon nitride case the temperature versus power curve is characterized by a hysteresis loop. With increasing power input the temperature first rises linearly and, at a certain input power, jumps to a much higher value due to ignition. When the power input is reduced the temperature decreases again but initially remains at a higher level and then, at a lower input power, jumps back to the previous curve. Due to its higher heat removal the reactor with the silicon membrane does not show such a hysteresis loop but a continuous increase of temperature with increasing power input.

For given boundary conditions, the different behavior of the two reactors results in a change in product composition of the Pt-catalyzed ammonia oxidation. NH_3 and O_2 are mainly converted to N_2 and NO in the silicon nitride membrane reactor, while significant amounts of N_2O were additionally observed in the silicon membrane reactor.

The investigations clearly show that microreactors allow reaction conditions to be achieved which are not feasible in macroscopic devices. For example, the silicon reactor can be operated in a regime between the ignition and extinction temperatures and give products different from those of a macroscopic device. This change in reaction products may also be of importance in other reactions such as ethylene oxidation and for reactions in the explosive regime in general.

The good agreement between measurement and simulation demonstrates that, at least for relatively simple devices and reactions, a theoretical prediction of the behavior of microreactors and, therefore, detailed optimization is possible.

4.5. Synthesis of a Vitamin Precursor in a Stainless Steel System with Simultaneous Mixing, Reaction and Heat Transfer

For the synthesis of a vitamin precursor a production process was established at BASF using a highly exothermic two-phase liquid/liquid reaction [39], [40], [49]. The two phases consist of hexane and concentrated sulfuric acid. The reactant, initially dissolved in hexane, reacts at the phase boundary to give an intermediate, which is then transferred into the sulfuric acid phase where the product is formed in a further reaction. The reaction is quenched after product formation by addition of water. A major problem of this process is the lowering of the yield by formation of byproducts in thermally induced side and consecutive reactions.

Initially, the synthesis was performed as a semi-batch process with a yield of 70 %. It was later replaced by a continuous process with a mixer and heat exchanger. The residence time in the mixer is 0.2 s and that in the heat exchanger 4 s. In spite of the short residence time, a temperature rise of 35 °C occurs in the mixer. Since this increase in temperature is half of the adiabatic temperature rise of the reaction, 50 % conversion is performed in the mixer. Completion of the reaction proceeds isothermally in the heat exchanger at 50 °C. The yield of the continuous process is 80 – 85 %.

In kinetic investigations with conventional laboratory techniques, the yield decreased dramatically to 25 %. This was attributed to the

Figure 32. Schematic representation of a T-shaped microreactor for ammonia oxidation manufactured by means of silicon micromachining and thin-film technology
A) Top view; B) Cross section of reaction channel, perpendicular to flow direction; C) Cross section of reaction channel, parallel to flow direction [70]

Figure 33. Reaction characteristics for ammonia oxidation in microreactors with low (left) and high (right) heat dissipation near the catalyst zone, demonstrated by power input/temperature curves [72]

fact that the whole procedure, including mixing of two phases, transfer of the heat of reaction, dilution with water, and phase separation, took two minutes. To obtain the desired information about the kinetics, a microreactor was designed and manufactured by IMM that allows the exothermic reaction to be carried out under nearly isothermal conditions [39], [40]. The design specifications were to limit the maximum temperature rise to 1 K and to achieve a total residence time of 4 s.

The five-plate microreactor is shown in Figure 34. Cavities between the bottom plate and the next plate contain four microstructured stainless steel platelets with an integrated mixer and heat exchanger system. The third plate has a delay loop which can be used for varying the residence time between 1 and 10 s. In the fourth plate the reaction is quenched by dilution of the concentrated sulfuric acid with water. This step is even more exothermic than the main reaction, but the product is no longer thermally sensitive under these conditions.

The stainless steel platelets integrating mixer and heat exchanger are the central elements of the reactor and were fabricated by means of a new micro discharge machining process developed at IMM, termed microerosive grinding (see Fig. 35) [73]. Eight heat exchanger channels, 60 µm wide and 900 µm deep, are surrounded by cooling channels machined into the back side of the platelets. Since the reactor con-

tains four of these platelets, the reaction is performed in 32 channels. Mixing is realized by intimate contacting of 32 partial streams of each reactant phase. Thus, mixing and reaction occur simultaneously. Since all volume elements flow along the same distance and hence have the same residence time, no backmixing takes place. The exclusion of backmixing in the microreactor should increase the product yield, since the labile product is sensitive to consecutive reactions.

Figure 34. Microreaction system for synthesis of a vitamin precursor comprising integrated static mixers, heat exchangers, reaction channels and delay loop [49], [73]

In the first experiments, the dependency of the yield on the residence time in a microreactor was analyzed at 50 °C (Fig. 36) [39], [40]. For a residence time of 4 s at 50 °C a yield of 80–85 % was found, which corresponds to that of the industrial process. For longer residence times a strong decrease in yield was found. For a residence time of 15 s, the yield decreased to ca. 65 %. This corresponds to the results obtained with conventional laboratory techniques, which inevitably result in long residence times (25 % yield).

In a more detailed optimization of yield and selectivity, the residence time was varied between 1 and 120 s, the operating temperature was decreased to 20 °C, and the exothermic reaction was run isothermally (Fig. 35). At an operating temperature of 20 °C and a residence time of 30 s a maximum yield of nearly 95 % was achieved, which considerably exceeds that of the continuous industrial process. The amount of byproducts is reduced by more than 50 % which clearly demonstrates the capability of microreaction technology.

Figure 35. Schematic of a platelet with integrated mixer and heat exchanger [73]

5. Outlook

Although current development work on microreaction technology is promising, it has to be emphasized that, in spite of a rapidly growing number of publications, this technology is still in its infancy. Some potential fields of applications such as electrochemistry [74], photochemistry [17], [20], and electrically steerable electrodes as dynamic catalysts [75] are just at the very beginning. Nevertheless, the most recent results make this technology even more promising, and the first announcements that chemical companies will utilize microreaction components for commercial processing have been made. Further impetus can be expected from developments in related fields.

Parallel organic synthesis of large numbers of compounds, often via complex reaction pathways or in very high purity, will inevitably require microreactor systems. Highly parallel polymerase chain reactions (PCR) are already performed in miniaturized reactors, and, with increasing complexity and automation, the potential growth is large. Progress in the field of microreaction technology in molecular biotechnology is described in [76–85].

A further driving force for the development of microreactor technology are mobile energy systems, especially fuel cells, with the aim of increasing the stored energy density by an order of magnitude. The development work deals not only with automotive applications but also with miniaturized fuel cell power supplies for mobile

Figure 36. Influence of residence time on the yield of a microreactor for synthesis of a vitamin precursor operated at 50 °C (left) and 20 °C (right) [40]

phones, laptop computers, and other portable electronic equipment. This work is also funded by defense organizations like DARPA in the United States [86], which expect advancement in mobility, safety, and comfort through microreaction technology.

Abstract

The article contains sections titled:

1. Introduction
2. Fundamentals of Ultrasound
2.1. Ultrasound in Liquids
2.2. Cavitation
2.2.1. Bubble Behavior in Acoustic Fields
2.2.2. Cavitation Thresholds
2.2.3. Parameters Influencing Cavitation
2.3. Nonlinear Effects
2.3.1. Bubble Collapse near Boundaries
2.3.2. Finite Amplitude Waves and Shock Waves
2.3.3. Streaming
2.3.4. Radiation Forces
2.3.5. Bjerknes Forces
2.3.6. Forces on Small Particles
2.4. Sonochemical Effects
2.4.1. Hot-Spot Theory
2.4.2. Shock Wave Theory
2.4.3. Supercritical Water Theory
2.4.4. Charge Theory
2.4.5. Promotion of Single Electron Transfer
2.4.6. Cleaning
2.4.7. Mechanical Activation
2.4.8. Enhanced Mass and Heat Transfer
3. Heterogeneous Systems
3.1. Solid - Fluid Reactions
3.1.1. Noncatalytic Reactions
3.1.2. Catalytic Reactions
3.1.3. Precipitation and Crystallization
3.1.4. Atomization
3.1.5. Disaggregation – Comminution
3.1.6. Cell Disruption
3.2. Ultrasonic Extraction
3.3. Liquid - Liquid Reactions
3.3.1. Emulsification
3.4. Phase-Transfer Catalysis

3.5. Sonoelectrochemistry
4. Homogeneous Systems
4.1. Aqueous Liquids
4.2. Nonaqueous Liquids
4.3. Polymers and Macromolecules
4.4. Sonoluminescence
5. Equipment
5.1. Transducer Technology
5.2. Reactors for Sonochemical Reactions
5.2.1. Laboratory Equipment
5.2.2. Large-Scale Equipment
5.3. Mapping of Sonochemical Reactors

Applications of ultrasound in processing and synthesis are widespread and offer unusual and beneficial operating conditions. Two major principles are used in sonochemistry or sonoprocessing: a) mechanical effects for mixing and disintegration and b) high energy processes for radical reactions. The fundamentals in ultrasound and the parameters influencing cavitation are explained.

In heterogenous systems, ultrasound is used in noncatalytic and catalytic reactions, biological applications, crystallization, emulsification, atomization, extraction, electroplating, phase-transfer catalysis. In homogeneous systems, applications of ultrasound include the preparation and degradation of polymers and macromolecules.

Mapping of sonochemical reactors can be achieved with several measuring systems and provides an essential knowledge about intensity distribution of the pressure field within the reactor volume.

1. Introduction

Applications of ultrasound in processing and synthesis are widespread and offer unusual and beneficial operating conditions. Two major principles are used in sonochemistry or sonoprocessing: a) mechanical effects for mixing and disintegration and b) high energy processes for radical reactions. Most effects occur in liquids, where sound pressures are able to disrupt the continuum. This generates oscillating bubbles, a process called cavitation. Cavitation is observed in shock tubes, pumps and other hydrodynamic devices. Due to the high frequencies in sonochemistry of between 16 kHz and several megahertz, the dynamics of oscillating bubbles create drastic conditions. Temperatures of several thousand Kelvin, extreme heating or cooling rates of 10^5 K/s, and pressures of up to several hundred megapascal are observed in a transient cavities while the bulk conditions in the liquid remain at ambient temperature and pressure. Radiation forces create intense micro and macromixing with high shear forces, which are used in emulsification, homogenization, and fragmentation processes. Asymmetrical bubble oscillations in the vicinity of solid particles lead to liquid microjets and shock waves, which are used in cleaning, dispersion, activation, and fragmentation of solid materials. Besides the main industrial applications in cleaning, emulsification, and welding, other uses of ultrasound, such as solids processing, atomization, crystallization, environmental protection and separation are emerging (Table 1). Some synthetic methods, for example the Barbier and Grignard reactions, have found industrial utilization. The growing interest in ultrasound application arises from the development of reliable ultrasound devices in the last years and the need for intensified and environmentally friendly processes with small safe reactor units, better energy yield, and enhanced chemical yield.

Table 1. Applications of ultrasound in processing

Field	Applications
Heterogeneous reactions	activation of solids in reactions, fragmentation, dispersion, agglomeration, preparation of catalysts, hydrogenation at room temperature
Homogeneous reactions	generation of radicals, oxidation of wastewater compounds, nanoparticle synthesis
Polymer processing	controlled degradation, initiation of polymerization, copolymerization, mixing in suspension polymerization
Electrochemistry	avoidance of mass transport limitations, electrode fouling, change in reaction pathways
Cleaning	cleaning of items in aqueous and nonaqueous media
Mixing	dispersion of solids, particle agglomerates, and pigments; mixing of immiscible liquids
Crystallization	initiation of seeding, control of particle size distribution, control of material

	properties
Extraction	fast and mild extraction of essential oils or microbiological material
Welding	welding of thermoplastics and metals
Cutting	cutting of ceramics and metals
Separation	improved filtration, agglomeration, and separation of particles

2. Fundamentals of Ultrasound

The term ultrasound describes sound waves with a frequency range from 16 kHz up to several megahertz [2]. Vibrational motions are transmitted by oscillating devices into a fluid and cause pressure waves. This varying sound pressure is superimposed on the static pressure of the liquid. Fluids are generally capable to transduce longitudinal waves, whereas solids also can show transversal motion. Above a critical sound pressure, liquids are disrupted by the applied sound pressure and so-called cavities are created. Most sonochemical effects are secondary effects generated by oscillating bubbles.

2.1. Ultrasound in Liquids

Sound waves in liquids are density and pressure waves in which particle oscillations occur in the direction of the wave (longitudinal waves). The displacement around the rest position causes compression and rarefaction disturbances which are transmitted to the connected layers (Fig. 1). The time-dependent particle displacement ξ the particle velocity v and the sound pressure p_a for plane waves can be described by:

$$\xi = \hat{\xi} \sin(2\pi f t) \tag{1}$$

$$v = \frac{d\xi}{dt} = \hat{v} \cos(2\pi f t) \tag{2}$$

$$p_a = \hat{p}_a \cos(2\pi f t) \tag{3}$$

with the maximum values of particle displacement, particle velocity and sound pressure indicated by circumflexes. In plane waves, the particle velocity v and the sound pressure p_a are related by the specific impedance of the liquid

$$\varrho_L c_L = \frac{p_a}{v} \tag{4}$$

which is the product of the liquid density ϱ_L and velocity of sound c_L.

Figure 1. Propagation of a traveling wave with density, normalized particle displacement, particle velocity and sound pressure as a function of normalized time or coordinate

The sound wave transports energy by kinetic energy of the oscillating particles. If we assume an energy density E given by

$$E = 0.5\, \varrho_L v^2 \tag{5}$$

which passes through a cross-sectional area S with the velocity of sound c we derive the so-called ultrasound intensity I as the energy flux per unit area:

$$I = 0.5\, \varrho_L c_L \hat{v}^2 = 0.5 \frac{\hat{p}_a^2}{\varrho_L c_L} \tag{6}$$

The determination of local intensities is quite difficult, and ultrasound devices are mostly characterized by calorimetric measurements. Sound pressure measurements and methods for determining the local intensity with coated thermocouples or by chemical means are still under development [1].

2.2. Cavitation

Sufficiently high sound pressures in liquids create voids or gas- and vapor-filled bubbles. Any liquid has a theoretical tensile strength which characterizes the minimum pressure for disruption. Due to the presence of nuclei such as dissolved gases, solid impurities, and rough walls, cavitation occurs at far lower sound pressures than are theoretically necessary. In nearly any liquid, initial nuclei are present which show a distinct size distribution and grow under a certain sound pressure. Bubble growth, multiplication, and disappearance in a sound field is still very complex phenomenon.

2.2.1. *Bubble Behavior in Acoustic Fields*

Several types of bubbles are present in cavitating liquids. Empty cavities (true cavitation), gas-filled cavities, vapor-filled cavities or mixtures of gas and vapor can be observed, depending on the applied sound pressure, static pressure,

temperature, and the nature of the used liquid. Some of these bubbles disappear because of dissolution of their contents under the sound pressure, some of them oscillate stably over several periods and others collapse violently, followed by the creation of smaller bubbles. The main task in sonochemical applications is the choice of the proper bubble behavior for the desired effect. Bubble motions in a sinusoidal sound pressure field can be described, for example, by the Rayleigh – Plesset equation

$$R\ddot{R}+\frac{3}{2}\dot{R}^2=\frac{1}{\varrho_L}\left\{\left(p_\infty+\frac{2\sigma_L}{R_0}-p_\nu\right)\left(\frac{R_0}{R}\right)^{3\gamma}+p_\nu-\frac{2\sigma_L}{R}-\frac{4\eta_L\dot{R}}{R}-p_\infty-p_a\right\} \quad (7)$$

which includes the surface tension σ_L, the liquid viscosity η_L, the polytropic exponent γ of the gas inside the bubble, the vapor pressure p_V and the initial bubble radius R_0 at rest. The solutions of this equation lead to nonlinear bubble wall motions (Fig. 2). A special case are resonant bubbles, which show damped oscillations. The resonant radius R_r of such a bubble can be described by Minnaert's formula

$$\varrho_L\omega_r^2R_r^2=3\gamma\left(p_\infty+\frac{2\sigma_L}{R_r}\right)-\frac{2\sigma_L}{R_r} \quad (8)$$

with the circular frequency $\omega_r = 2\pi f$.

Figure 2. Total pressure (top) and solution of the Rayleigh – Plesset equation for bubble radius (bottom) of a stable bubble as a function of time for air saturated water at 20 kHz with an initial bubble radius R_0 of 0.1 mm, a static pressure of 0.1 MPa and a sound pressure of 0.1 MPa

2.2.2. *Cavitation Thresholds*

A more illustrative description of the bubble motion in an acoustic field can be introduced by the concept of cavitation thresholds for different types of bubble behavior [10]. Depending on the nature of the motion four basic types of cavitating voids are distinguished (Fig. 3):

- Stable cavitation
- Rectified diffusion
- Dissolving bubbles
- Transient cavitation

Figure 3. Simplified cavitation thresholds and regions for air saturated water at a static pressure of 0.1 MPa at frequencies of 20 and 500 kHz

In the absence of an acoustic field, a gas bubble in a liquid will slowly dissolve owing to the excess internal pressure required to withstand the surface tension pressure $2\sigma_L/R_0$. By applying a changing pressure, the dissolution time can be increased. Very small bubbles will still dissolve, but some bubbles larger than a certain threshold radius can be stabilized in the sound field. These stable oscillating bubbles survive several acoustic cycles. In a process, known as rectified diffusion, such bubbles collect gas from the liquid and grow in size. In the rarefaction cycle, the bubble radius increases and volatile gases or vapor can enter the bubble across the interface. In the following compression cycle, the bubble shrinks, and the diffusion of gases into the liquid is hindered by the smaller exchange surface. This effect is aided by the changing thickness of the liquid boundary layer, which generates high concentration gradients at large radii and small gradients in the compression phase. Rectified diffusion is responsible for the degassing of liquids under ultrasound, even at low sound pressure of 0.01 MPa. Such a growing bubble may reach the resonance radius, at which very strong oscillations cause surface instabilities and the generation of smaller bubbles. Surface oscillations are responsible for very high microstreaming in the vicinity of stable bubbles, which accelerates heat and mass transport. The behavior of some bubbles can change dramatically at a certain radius. The radius grows rapidly to more than twice the size in half an acoustic period. This is followed by a sudden collapse after which the bubble disappears. These bubbles are known as transient bubbles (Fig. 4) and cause most of the sonochemical effects.

Figure 4. Bubble radius as a function of time for a transient cavity with an initial radius of R_0 = 1 µm, a static pressure of 0.1 MPa, and a driving sound pressure amplitude of 0.4 MPa in air-saturated water. The maximum bubble radius decreases with increasing frequency

Transient bubbles have a very small collapse time which was first deduced by RAYLEIGH. An approximation for the collapse time in acoustic sound fields is

$$\tau_B = 0.915 \cdot R_{max}\left(\frac{\varrho_L}{p_m}\right)^{\frac{1}{2}}\left(1+\frac{p_v}{p_m}\right) \tag{9}$$

where R_{max} is the maximum bubble radius before collapse, p_m the mean driving pressure (the sum of hydrostatic and sound pressure), and p_V the vapor or gas pressure inside the bubble at maximum expansion. Transient bubble generation is subject to two restrictions: First, a transient bubble must undergo extensive growth, for which its radius must exceed a certain threshold at which the forces acting on it are higher than the surface tension forces. Secondly, having reached this state, sufficient energy must be concentrated in a very short time, and this requires critical values of the radius before (R_{max}) and after collapse (R_{min}). Only in this case, are the energy dissipation (heat conduction, viscosity losses) smaller than the work done by the spherical convergence of the surrounding liquid. These two criteria are described by the so-called Blake threshold radius $R_{B,0}$ and the Flynn dynamic radius $R_{F,0}$. Bubbles having initial radii R_0 smaller than the Blake threshold and greater than the Flynn dynamic radius will undergo transient collapse. APFEL used these criteria and derived an expression for the maximum bubble radius before collapse.

$$R_{max} = \frac{4}{3\omega}(\hat{p}_a - p_\infty)\sqrt{\frac{2}{\varrho_L \hat{p}_a}} \left(1+\frac{2}{3p_\infty}(\hat{p}_a + p_\infty)\right)^{\frac{1}{3}} \tag{10}$$

Assuming isothermal expansion to maximum bubble radius R_{max} and subsequent adiabatic collapse, the pressures and temperatures generated in a gas-filled transient cavity can be derived as

$$T_{max} = T_0(\gamma - 1)\left(\frac{R_{max}}{R_0}\right)^3 \tag{11a}$$

$$p_{max} = p_{g,m}\left(\frac{p_\infty(\gamma-1)}{p_{g,m}}\right)^{\frac{\gamma}{\gamma-1}} \tag{11b}$$

where $p_{g,m} = p_\infty(R_0/R_{max})^3$ is the pressure in the bubble at maximum radius.

2.2.3. *Parameters Influencing Cavitation*

Influencing parameters in sonochemical applications are listed in Table 2.

Table 2. Important influencing parameters in sonochemical applications

Parameter	Property	Effect
Dissolved gas	polytropic ratio	cavitation intensity
	thermal conductivity	primary sonochemistry
	solubility	cavitation intensity
Vapor pressure	content of bubbles	cavitation intensity
Liquid viscosity	dissipative effects	cavitation intensity
Temperature	liquid properties	cavitation intensity
	thermal activation	secondary reaction rate
Static pressure	thresholds	cavitation intensity and
	gas solubility	extent of cavitation zone
Frequency	thresholds	cavitation intensity
	wavelength	extent of cavitation zone
Intensity	thresholds	cavitation intensity
	attenuation	extent of cavitation zone
	maximum bubble radius	cavitation intensity

Dissolved Gases are present in most applications of ultrasound. The type and amount of these gases in the treated liquid are a very important factor for the sonochemical effects [11]. Highly gas saturated liquids have large numbers of cavitation nuclei and low cavitation thresholds. Degassed liquids need higher sound pressures for cavitation, but the sonochemical effects are in most cases more intense. The bubbles can collect gas from the surrounding liquid, and this rectified diffusion creates large bubbles with high gas contents. On collapsing, these bubbles create only moderate temperatures and pressures. As a general rule, degassing a liquid is always favorable in sonochemical applications. Beside the gas content of a cavitating bubble, the used gas is important (Table 3). Gases with high polytropic exponents and small thermal conductivity show the best effects under sonication. Monoatomic gases like argon and xenon exhibit good cavitation intensities, whereas diatomic gases such as nitrogen and oxygen tend to decrease the observed effects. Gases with high thermal conductivity

such as helium decrease the intensity of cavitational collapse to nearly zero.

Table 3. Properties of different gases and their influence on H_2O_2 yield and sonoluminescence intensity

Gas	Specific heat ratio γ	Thermal conductivity, $mWm^{-1}K^{-1}$	Solubility in water at 20 °C, mL/100 mL H_2O	Relative H_2O_2 yield [11]	Relative sonoluminescence intensity [5]
Nitrogen	1.40	25.83	2.33	2.5	45
Oxygen	1.40	26.46	4.89	13.5	35
Helium	1.65	149.68	0.94	1	1
Neon	1.67	48.02	2.6	7	18
Argon	1.67	17.75	5.6	21.5	54
Krypton	1.67	9.46	11.0	24.0	180
Xenon	1.67	5.19	24.1	27.5	540

Vapor Pressure. The vapor pressure of liquids can cushion the bubble collapse like a high gas content. Vapor in a transient bubble can be condensed in the compression cycle and lead to higher cavitation intensities than gas filled bubbles. Experiments with different solvents show that small vapor pressures are necessary for a sufficiently high cavitation intensity. Higher vapor pressures, especially near the boiling point of the liquid, can dampen the cavitation efficiency to nearly zero. If a substrate is subject to treatment within the collapsing bubbles, then a certain amount of its molecules must be present in the bubbles and exert an at least measurable vapor pressure. The existence of molecules inside the bubble can easily be proved by means of molecules which exist as ionic or molecular species at different pH values. Ionic species do not enter the bubbles, and high temperature pyrolysis products can therefore not be created.

Viscosity. High viscosity of a sonicated liquid increases the cavitation threshold markedly. Viscous liquids generate bubbles only at high sound pressures. Bubble motion is damped by the dissipative effect of the viscosity and the smaller maximum bubble radii, and the lower inward wall velocities terminate most sonochemical effects.

Temperature. The effect of temperature on sonochemical processes is explained by its influence on viscosity, gas solubility, vapor pressure and surface tension. Any chemical reaction will be influenced by the temperature-dependent reaction rate coefficient. In most cases, cavitation is more pronounced at lower temperatures due to the lower vapor pressure of the liquid. This lowers the total gas content of the collapsing bubbles and causes higher cavitation intensities. This paradoxical temperature dependence is highly pronounced for sonochemical reactions involving radical generation in transient bubbles. Lesser effects are generally observed in heterogeneous systems, where intense micromixing by oscillating bubbles favors mass and heat transfer.

Static Pressure. The static pressure in a sound field alters the thresholds for rectified diffusion, transient bubbles and other characteristics. A high static pressure can prevent the generation of bubbles by ultrasound or create a different size distribution. For a given amount of energy, smaller bubbles with a higher energy content are created, which show very strong erosion activities in heterogeneous systems.

Frequency. The effect of frequency on sonochemical reactions is still an active field of research. Some measurements indicate that different frequency ranges are needed for special reaction types. Low frequencies in the range from 16 to 100 kHz, known as power ultrasound, are mainly active in heterogeneous systems with micromixing, cleaning, mechanical action on suspended solids and intense bubble motion. High frequencies favor high temperatures and pressures in the cavitation bubbles, thus creating a large number of radicals. The sonolysis of water seems to be most pronounced at frequencies between 300 and 500 kHz. Frequency is a very important parameter in defining whether a bubble of a given size is transient or stable. The smaller bubbles present in a high frequency sound field have a lower energy content than the larger bubbles generated at low frequencies. Beneficial for sonochemical effects is the higher number of cavitational events in high-frequency applications. In nearly all sonochemical processes, an optimum frequency can be found experimentally.

Ultrasound Intensity. The effect of intensity or power input to the ultrasonic device is complicated. Higher intensities provoke a larger amplitude at the vibrating surface in contact with the liquid. At low intensities, a linear dependency between generated sound pressure and amplitude is observed. Raising this intensity above the cavitation threshold of the liquid causes oscillating bubbles, and under certain circumstances the contact between radiating surface and liquid is lost. The motion of the transducer and the liquid are out of phase, an effect known as decoupling. A second reason for the nonlinear relationship between intensity and sonochemical effects is the creation of cavitation zones. Higher intensities create more and larger bubbles, which may coalesce and lead to less transient events. Energy efficiency and sonochemical effects are therefore sometimes smaller at higher intensities, and often the optimum intensity for a specific sonochemical effect must be determined experimentally.

Pulsed Ultrasound. Pulsed ultrasound is characterized by phases with and without ultrasound. In the ultrasound cycle, bubbles are created, grow by rectified diffusion, and may eventually collapse. The silent cycle can be used to remove larger bubbles by Archimedian forces. Smaller bubbles begin to dissolve, and the overall gas content decreases, giving optimum conditions for the next sonication cycle. Many sonochemical processes benefit from pulsed operation and show better performance than with continuous operation.

2.3. Nonlinear Effects

2.3.1. *Bubble Collapse near Boundaries*

Undisturbed bubbles in liquids show spherical oscillations in a sound field [12]. Any extended disturbances such as boundaries, suspended solids, or reactor walls in the vicinity of the transient bubble prevent spherical collapse. Asymmetric bubble wall motion leads to the formation of an involution, which is directed towards the disturbance. In the late stages of the collapse of a transient bubble, a liquid microjet breaks through the remote bubble wall and impinges on the boundary. Liquid microjets can reach velocities in the range of several hundred meters per second and are responsible for cavitation erosion on solids. The pressures generated on solid surfaces can melt soft metals, create pitting, or disrupt inorganic layers on metals. A liquid jet with a diameter of roughly one tenth of the collapsing bubbles diameter creates a water hammer p_{WH} pressure of

$$p_{WH} = \frac{(\varrho_L c_s \varrho_T c_T)\, v_J}{\varrho_L c_s + \varrho_T c_T} \tag{12}$$

where c_S is the shock speed ($c_S \approx c_L + 2v_J$), v_J the jet speed, c_T the speed of sound and ϱ_T the density of the target. This pressure is maintained in the center of the jet for a time $t_{col} = R_{max}/10c_S$ followed by a Bernoulli pressure of $\varrho_L v_J^2/2$. Most heterogeneous reactions make use of these mechanical effects in cavitating sound fields. Even more intense effects are observed when clouds of bubbles collapse near solid boundaries. The concerted breakdown of such a hemispherical transient bubble cloud generates shock wave pressures and jetting with intensities some orders of magnitude higher than those of single bubbles [13].

2.3.2. *Finite Amplitude Waves and Shock Waves*

Most applications in ultrasound deal with rather small particle velocities v. This can be described by the acoustic Mach number $M = v/c_L$. A 20 kHz high-intensity step horn with an amplitude of 100 µm creates a Mach number of about 0.01. For low Mach numbers, the acoustic approximation of incompressible liquids is applicable. In certain cases, for example focused sound fields, much higher Mach numbers are present and lead to distortion of the sinusoidal wave form. Density and sound pressure no longer satisfy a simple linear equation with a fixed speed of sound c. A pressure-dependent speed of sound is observed (material nonlinearity). Convective terms in the equation of motion cannot be neglected at higher Mach numbers and lead to a more complicated situation (convective nonlinearity) in which the real speed of the wave front consists of two parts, the speed of sound c and the particle velocity v. The material nonlinearity and the convective nonlinearity tend to increase the propagation velocities of zones with high pressures. This leads to saw-tooth waveforms which develop a shock wave. Consisting of higher harmonics of the initial sound frequency, these saw-tooth waves are strongly attenuated and quickly decay into low-amplitude sinusoidal waves with the initial frequency. Shock waves are also formed in transient bubble collapse. If the bubble wall reaches high velocities, a shock wave is emitted into the surrounding liquid. The Mach number in this case is $M = (dR/dt)/c_L$ and reaches values higher than unity. The shock wave is generated some distance from the bubble. Hickling and Plesset calculated, that above a pressure of 100 MPa inside the bubble, a shock wave starts at a distance of $r/R_{min} = 5 – 6$ where R_{min} is the minimum bubble radius at collapse [14].

2.3.3. *Streaming*

Acoustic Streaming. As an acoustic wave travels through a medium, it can be absorbed. Because of the absorption of momentum in the direction of the sound field, flow is initiated in this direction. Local variations in intensity and energy absorption lead to local streaming velocities in the order of several centimeters per second. Finite amplitude waves create acoustic streaming due high absorption of higher harmonic components.

Acoustic Microstreaming. Small obstacles in a sound field create circulation by friction between their boundaries and the vibrating liquid particles. This acoustic microstreaming boundary layer has a thickness δ_{MS} of

$$\delta_{MS} = \sqrt{\frac{2\eta_{L,S}}{\varrho_L \omega}} \tag{13}$$

where $\eta_{L,S}$ is the shear viscosity of the liquid. Microstreaming enhances mass and heat transfer and leads to shear forces on the obstacles.

2.3.4. *Radiation Forces*

Objects in an acoustic sound field experience a force whose magnitude and direction depends on the intensity of the source if the dimensions of the target are greater than the wavelength. Two types of radiation forces can be distinguished, depending on the boundary conditions. The Rayleigh radiation force acts on a target of area S in a closed vessel with energy density E:

$$F = 0.5\,(1+\gamma)\,ES \tag{14}$$

The case of open vessels (free boundary condition) is treated by the Langevin radiation force

$$F = ES \tag{15}$$

which represents most experimental conditions. The Langevin radiation force is utilized to measure the intensity of sound fields.

2.3.5. *Bjerknes Forces*

Stable oscillating bubbles experience translational radiation forces in a traveling-wave field. In standing-wave fields, these so-called primary Bjerknes forces act on oscillating bubbles and are due to a time-average force resulting from sound field pressure gradients and bubble oscillation. Bubbles below resonance size are attracted to pressure antinodes, whereas

bubbles above resonance size travel down pressure gradients towards pressure nodes (Fig. 5) [33].

Figure 5. Normalized sound pressure, particle displacement and primary Bjerknes forces acting on bubbles smaller and greater than the resonance radius R_0. Small bubbles collect in pressure antinodes (displacement nodes), whereas large bubbles travel toward pressure nodes

Secondary Bjerknes forces arise when two oscillating bubbles are present in a pressure field. Attractive forces between bubbles with in-phase pulsation cause coalescence. Bubbles oscillating out of phase are repelled. The bubble oscillation is in phase when both bubbles are smaller or larger than resonance size and attractive forces dominate. If one bubble is smaller and one larger than resonance size, they oscillate in out of phase and repel one another.

Primary and secondary Bjerknes forces lead to structures known as cavitation streamers. A large bubble above resonance size oscillating with surface instabilities and located in a pressure node generates microbubbles below resonance size, which are repelled and forced towards the pressure antinode of a standing-wave field, where attractive forces cause clouds of oscillating microbubbles. The lines of microbubbles are often called microstreamers.

2.3.6. *Forces on Small Particles*

Small particles with radii smaller than the cavitation bubbles are accelerated in the velocity and pressure gradients around oscillating bubbles. These forces are even greater when particles are subject to shock waves. Particle velocities of up to 500 km/h can be reached. On collision of two such particles, oxide layers are removed and metals are melted together. Such treated metals are used in catalysis, where activity enhancements by a factor of up to 10^6 are observed.

Like the Bjerknes forces, solid particles whose acoustic properties differ from those of the liquid are subject to primary and secondary forces. Primary forces drive particles into pressure nodes, where secondary forces between particles are responsible for further aggregation [15].

2.4. Sonochemical Effects

The effects of ultrasound on chemical reactions are in most cases secondary effects caused by cavitation and can be divided into five main groups:

1. Reactions inside the cavitation bubble at high temperatures and pressures
2. Reactions at the gas – liquid interface of the bubbles (secondary reactions of products formed within the bubbles, high-temperature reactions of nonvolatile liquids)
3. Reactions due to high pressures in the surrounding liquid
4. Effects caused by nonlinear bubble collapse near boundaries
5. Enhanced mass and heat transfer by macro- and micromixing

2.4.1. *Hot-Spot Theory*

Very high temperatures and pressures are generated in a cavity on collapse. Noltking and Neppiras calculated temperatures of up to 10^4 K in a transient cavity. This would lead to black-body thermal radiation which can be observed spectroscopically. Temperatures of 5000 K in the bubble, 2000 K in the liquid boundary layer and pressures of 50 MPa were found in experiments with metal carbonyles [5]. UV/Vis spectroscopy of the cavitating liquid showed good agreement with the thermal spectra of carbon and the metals at the same temperature. Thus, by creating extreme temperatures in transient bubbles and the surrounding liquid boundaries, high-temperature reactions can be initiated in a liquid that remains at ambient temperature. These calculations are confirmed by the presence of pyrolysis products of irradiated liquids. These include the homolytic cleavage of water, the cleavage of carbon-halogen bonds, and the production of radical products from organic liquids like alkynes and alkenes. The extreme heating and cooling rates of about 10^5 K/s resemble those in the freezing of molten metals when poured onto a plate with a temperature of – 270 °C. Under the extreme conditions of a transient bubble, even plasma reactions or fusion were proposed. Theoretically, conditions similar to those on the surface of the sun are possible.

2.4.2. *Shock Wave Theory*

The compression of transient bubbles leads to an increasing bubble wall velocity which may eventually reach the speed of sound of the liquid. In true transient cavitation, the bubble vanishes after collapse, creating a shock wave in the liquid. Particles and macromolecules are accelerated in the steep pressure gradient and are shock fragmented. High speed particles collide and undergo mechanical damage.

2.4.3. *Supercritical Water Theory*

High temperatures and pressures in aqueous sonochemistry may lead to conditions under which supercritical water is likely. Supercritical water is known to have a strong solvent action towards organic compounds and extreme chemical activity. Sonochemical effects are possible inside the supercritical water layer surrounding a transient bubble. At the time being, no direct evidence for the generation of supercritical water in ultrasound fields has been found experimentally.

2.4.4. *Charge Theory*

Russian workers questioned the existence of true cavitation and postulated a somewhat different sonochemical effect. Oscillating bubbles undergo very rapid size changes. Friction forces at the gas-liquid bubble boundary can create charged

species which can lead to secondary chemical reactions in the bulk liquid.

2.4.5. *Promotion of Single Electron Transfer*

Classical ionic bimolecular nucleophilic substitution reactions (S_N2) have been interpreted as a radical mechanism with radical formation by transfer of a single electron according to

$$RX + Y^- \rightarrow RX^{\cdot -} + Y \qquad (16)$$

Ultrasound has a accelerating effect on such single-electron transfer reactions (SETs) and can alter the reaction pathways when ionic S_N2 reactions and SET reactions occur simultaneously and lead to different products.

2.4.6. *Cleaning*

Microstreaming, shock waves, and liquid microjets in the vicinity of solid surfaces lead to very efficient cleaning. This effect has been used in industry for more than forty years. Insoluble layers of inorganic salts, polymers, or liquids can be removed by ultrasonic cleaning effect. In heterogeneous systems such a clean reactive surface leads to improved dissolution rates of metals in acids and enhanced reaction rates. Chemical reactions giving insoluble products are freed from these mass transport limiting layers and react rapidly.

2.4.7. *Mechanical Activation*

Several mechanisms for the activation of solids in chemical reactions are induced by the mechanical effects of ultrasound and transient cavities. High intensity ultrasound is able not only to remove passivating layers on solids, but to break solids like salts and metals as well (Fig. 6).

Figure 6. Influence of transient bubbles on particles of different size in a 20 kHz sound field. Extended surfaces lead to asymmetrical collapse with formation of microjets. Medium-sized particles to less asymmetrical collapse. Small particles are accelerated by bubble oscillation and in the shock wave

Surface Renewal. Impacting liquid microjets or shock waves create the pitting on solid surfaces [17]. These indentations are free of unreactive layers and react readily with dissolved reactants. Mechanical energy is introduced to the lattice of the solid and leads to slightly excited active centers. In general, such activated solids exhibit higher reaction rates than the untreated solids.

Particle Disruption. Brittle solids can be cleaved by transient cavities. Like in milling operations, this leads to higher specific surfaces, high energy content at the disrupted site, and reactive fresh surfaces. Because of the tiny bubble size, very small particles in the micrometer range can be produced.

Particle Agglomeration. Acceleration of small particles in the shock wave field of a transient bubble can lead to particle agglomeration. Highly accelerated particles collide and melt together on contact. Contact temperatures of nearly 3000 K were measured for very small particles. Particle agglomerates in the vicinity of transient bubbles are fragmented and yield higher specific surfaces [16]. Primary and secondary forces on suspended solids can increase the amount of aggregation in pressure antinodes of a standing wave field. These effects are used, for example, in separation processes.

2.4.8. *Enhanced Mass and Heat Transfer*

Many heterogeneous reactions are accelerated by the enhanced micromixing properties of cavitating sound fields. Oscillating and transient bubbles create intense microstreaming in the vicinity of suspended solids. Macromixing is induced by acoustic streaming and the oscillation of bubbles in the sound field. In most cases, a locally different mass transport coefficient is observed. Tenfold increases in mass-transfer coefficients compared with silent reactions were measured [18].

[Top of Page]

3. Heterogeneous Systems

3.1. Solid – Fluid Reactions

In heterogeneous solid – fluid reactions, asymmetrical bubble collapse creates shock waves and liquid microjets. These are responsible for particle fragmentation, pitting, and cleaning of the solid (see ⟶ Metals, Surface Treatment – Cleaning). Particles that are larger than the transient cavity must be present to induce asymmetrical collapse. Powdered solids which are smaller than the transient bubble are accelerated in the shock waves surrounding a cavity. High impact speeds lead to cleaning, shock fragmentation and mechanical activation. Metal particles in the micrometer range are melted together. Only tungsten (*mp* 3410 °C) resists aggregation by welding [19]. In a 20 kHz sound field for example, extended particles have to be roughly 200 µm in size to perturb the radial collapse. In this case, loss of material and some surface hardening of metals is observed. Surface hardening is due to an increasing lattice deformation with higher defect density on the surface of the solid. This high defect density also leads to a better chemical reactivity for specific reactions and facilitates syntheses by solid – fluid reactions, especially in organometallic chemistry.

3.1.1. *Noncatalytic Reactions*

Alkali metals are often used in synthesis and are very suitable for ultrasonic processes [8]. Passivating layers on the pure metals are removed, and the induction times of reactions are shortened dramatically. Aromatic radical anions like naphthalene – lithium, anthracene – sodium or biphenyl – sodium are easily formed under ultrasound [9] in 45 min, compared

to 48 h without ultrasound. Very fine dispersions of sodium and potassium are possible in solvents with low vapor pressures such as toluene or xylene. Dispersed colloidal metals are used in Dieckmann condensations and Wurtz coupling.

The Barbier reaction needs under classical conditions dried solvents like THF or ether, an organic chloride, and lithium wire or powder [20]. With ultrasound, moist solvents can be used. A reduction of induction time, high reaction rates and high selectivity are observed because sonication is performed under mild conditions below the boiling point of the solvent. In most cases, no difference in the total yield was observed. One of the advantages of the Barbier reaction is the possibility to produce highly unstable intermediates in situ which will react with a second reagent:

(17)

The Bouveault Reactions of alkyl, cycloalkyl, and aryl bromides with Li and DMF in ether solvents to form aldehydes is drastically enhanced by ultrasound, and high selectivity is observed [8]:

(18)

This special case of a Barbier reaction shows no reaction at an ultrasonic frequency of 50 kHz in diethyl ether, but reasonable yields at 500 kHz. This unexpected frequency effect can not be explained by cavitation and remains one of the open questions of sonochemistry.

Magnesium is used widely in the synthesis of Grignard reagents. Fast reactions and virtual absence of induction times under sonication allow safe and easy production of these valuable intermediates [21], [22].

(19)

Sonication experiments on 2-bromobutane revealed a 60-fold increase in reaction rate even in impure wet ether [23]. Bogdanovic et al. developed a method to prepare a highly reactive magnesium-anthracene complex. Using this activated magnesium Mg*, a variety of Grignard reagents can be produced:

(20)

Grignard reagents are often used for transmetalation reactions to prepare less readily accessible organometallic compounds such as organoboranes and organozinc compounds.

Aluminum. Improvements in reaction rate and yield have been reported for the preparation of alkyl aluminum halides. An interesting result was the reaction of bromoethane with Al in THF to give ethylaluminum sesquibromide under ultrasound, which is not observed under stirring conditions.

Zinc. The direct formation of organozinc compounds from zinc and halides is possible, but transmetalation with Li is more reliable:

(21)

The Simmons-Smith cyclopropanation of alkenes with diiodomethane or dibromomethane and Zn benefits from ultrasound. Whereas under ultrasound 98 % yield after 2 h of irradiation are measured, only 50 % yield is possible in the stirred reaction.

A sonochemical variant of the Reformatzky reaction for the synthesis of β-hydroxyesters or β-lactams has been reported to give excellent yields compared to traditional methods using activated zinc or cosolvents. Allylations of carbonyl compounds

can be performed in an H_2O/THF/Zn slurry. Substantial rate enhancements are observed in the dehalogenation of aryl halides with zinc in aqueous HMPA with nickel(II) chloride. Cross coupling of perfluoroalkylzinc reagents with halides is possible.

Copper. Copper can be activated in an acoustic field to allow reaction at moderate temperatures. The Ullmann coupling reaction requires high temperatures. Sonicated copper is fragmented and cleaned to give highly reactive fresh surfaces and a 64-fold increase in reaction rate:

(22)

Nonmetals. In most reactions of nonmetals suspended in a liquid phase, the solid phase serves as one of the reagents and is consumed. Low solubility and slow reaction rates are common. Under ultrasound, a quasihomogeneous mixture is created by intense particle fragmentation and high mass transfer coefficients. Strong bases like KOH or NaOH are readily fragmented and undergo very fast and selective reactions. Oxidations of alcohols with potassium permanganate in benzene do not need water as a cosolvent under sonication. ANDO et al. [7] were able to activate manganese dioxide in a presonication process to give a material which oxidizes several alcohols. Quite unusual reductions of heteroatom-halogen bonds have been reported. Lithium aluminum hydrides are used to substitute aromatic halides in excellent yields.

CONTAMINE et al. [34] examined the Michael addition of a diethyl malonate anion to the double bond of phenyl styryl ketone. Solid KOH is used to promote the reaction in toluene. Two rate-limiting steps, the formation of a carbanion and its addition to the double bond, which is interpreted as a single electron transfer (SET), are likely. Under ultrasound, very fast reaction is observed and explained by enhanced mass transfer and KOH fragmentation, removing the first limiting step, and the influence of ultrasound on SET reactions.

3.1.2. *Catalytic Reactions*

Catalyst Preparation. Sonication has been applied to the preparation of catalysts for a wide range of processes. Hydrogenation catalysts like Pd/C, Pt/C, and Rh/C show better reactivity after mechanical activation and higher specific surface areas due to cleavage of the support. These activated catalysts are used in hydrogenation of alkenes, acetophenone, methylstyrene, and fat hardening. A remarkable increase in activity was found by SUSLICK [25], who sonicated Ni powder for up to 1 h in 1-octene. The metal showed a very clean surface (removal of Ni oxide) and a 10^5-fold activity, like freshly prepared Raney Ni, but a smaller specific surface area after prolonged sonication due to agglomeration.

Unusual catalysts are prepared by sonication of solutions of metal carbonyls in alkanes. Fe, Ni, Co, and Mo carbonyls give nanostructured amorphous metal or metal carbide powders.

Sonicated Catalytic Reactions. Inorganic supports like alumina, silica gel, and zeolites promote nucleophilic substitution with alkali metal cyanides in organic solvents. ANDO et al. [26] discovered the sonochemical switching of a reaction pathway in the reaction of benzyl bromide with potassium cyanide and alumina in toluene. While stirring leads to a mixture of the Friedel-Crafts products, benzyltoluenes, ultrasonic irradiation promoted nucleophilic substitution to give benzyl cyanide. It was concluded, that cyanide had poisoned the active Lewis acid sites, therefore decreasing the catalytic activity of the alumina.

(23)

Hydrogenations of alkenes by formic acid or hydrazine and palladium-carbon with in situ generation of hydrogen have been reported [9]. Commercial applications such as the hydrogenation of soybean oil and fat hardening in three-phase processes have already found industrial utilization.

3.1.3. *Precipitation and Crystallization*

The application of ultrasound influences the nucleation, agglomeration, and growth of particles within the liquid phase. The main aim of the application of ultrasound in crystallization is the formation of a narrow particle size distribution [3], [35]. The sonication induces the homogenous nucleation in the sonicated volume [36], [37]. The nuclei are supposed to be of the same size, which is an advantage to the conventional seeded crystallization, which uses a seed suspension. This seed suspension

itself possesses a nonuniform particle size distribution, which is transferred to the crystallized product. High-power ultrasound promotes and improves nucleation and growth of crystals by cavitation bubbles, the disruption of seeds, and the breakage of larger crystals. There is some evidence that the sonication of supersaturated solutions leads to creation of highly uniform nucleation sites by disturbing the metastable equilibrium. The enhanced micromixing avoids nonuniform concentration gradients in the solution. Further on, sonocrystallization is applied to control the shape and structure of a crystal, called polymorphic controll. This plays an important role in the field of soft, i. e., biological materials like proteins or fatty acids [38]. Industrial applications of homogenous nucleation due to ultrasound are found in the frozen food industry, where even seeding prevents the disruption of cellular materials on freezing.

Precipitation is primarily controlled by the mixing of two solutions. The more homogenous the mixture is the smaller particles can be synthesized [39]. The application of ultrasound provides the possibility of intense and controlled mixing in the microscale. In contrast to flow reactors like T-mixer, rotor–stator mixer, and impinging jet mixer, the mixing with ultrasound is decoupled from the flow field. The specific power induced for mixing can directly be controlled by the power consumption of the ultrasound generator. Cavitation allows local high-power dissipation and with it intense micromixing. The process usually is designed that the reactants are directly injected into the cavitation zone. A second method uses a reactant like urea, which decomposes during sonication, to induce the precipitation process.

Particle synthesis due to the reduction of dissolved ions also applies ultrasound. The synthesis of gold nanoparticles [35] uses the presence of radicals, which in a second step act as a reducing agent to form the metal nanoparticles. The formation rate of the metal nanoparticles can be influenced by additives, which act on the radical formation rate.

3.1.4. *Atomization*

The production of atomized sprays from a liquid is facilitated by the use of ultrasonic devices. Normally, sprays are produced by forcing high-velocity liquids through a small aperture. Blockage and nonuniform size distributions are often observed. The initial velocity of the produced spray tends to form clusters. Ultrasonic devices make use of high velocity changes on a vibrating tip. The particle size can be controlled by either the frequency or the intensity of the ultrasonic horn. Materials like molten glass or metal are easily atomized, show a very narrow size distribution, and have a very low particle velocity.

3.1.5. *Disaggregation – Comminution*

The governing effect on size reduction is cavitation. Agglomerates of lower stability also are affected by the pressure waves of the acoustic field. The process parameters and the theoretical description derive from the conventional milling theory [40], [41].

$$x_{50,3} = C \cdot (E_v)^{-b} \tag{24}$$

where $x_{50,3}$ is the mean volume particle size in nm, C is a characteristic constant, E_v is the specific energy (kJ m^{-3}). The exponent b has to be drawn fron the plot $x_{50.3}$ versus log(E_v).

The process depends on the specific energy consumption, the specific power input of the transducer and the residence time.

Ultrasonic disagglomeration can be combined with conventional milling equipment. Sonication after a communution process is able to downsize agglomerates formed directly after the mechanical milling or agglomerates damaged by the mechanical stress [42].

3.1.6. *Cell Disruption*

The main effects of ultrasound which occur during biological applications are cavitation and heating of the medium. The heating is an immanent effect due to the absorption of the wave energy within the medium [43]. Considering biological molecules (proteins), their high sensitivity to thermal changes has to be taken into account (see ⟶ Enzymes – General Production Methods, Table 2). The application of ultrasound in biological systems usally is accompanied by an intense cooling. The heating depends of the distribution of the ultrasonic waves into the medium and its heat-transfer properties. Heat also is generated during cavitation. Because of the inhomogenity of biosystems, sufficient nuclei for bubble formation are present.

The mechanical action of cavitation typically causes cell lysis, disintegration, or defragmentation. At lower ultrasonic intensity, just above the cavitation threshold [44], subtle damages of the cell membrane occur, which lead to an increased permeability of macromolocules through the membrane. This effect is called sonoporation or permeabilization. Sonoporation is used to load cells with large molecules, i.e., DNA [45] or drugs.

With further increasing ultrasound intensity, the cavitation intensity and with it the mechanical stress acting on the cell membrane increases as well. The duration of sonication of a cell suspension can influence the quality of the obtained biosuspension. With increasing sonication, the activity of liberated proteins can decrease [46]. The main process parameters for cell disruption are: ultrasound intensity, duration of sonication, process temperature, protein/enzyme yield, protein/enzyme activity.

3.2. Ultrasonic Extraction

Ultrasonic extraction processes from biological cells, bacteria, microorganisms, or plants are used in research as well as on an industrial scale [5]. Cell disruption, enhanced micromixing, and impregnation of material by liquid microjets reduces processing time and allows less harmful solvents to be used for extractions. The normally lower temperatures allow very mild processing with high yields of alkaloids, essential oils, glycosides, and fragrances.

3.3. Liquid – Liquid Reactions

Only a few examples of the influence of ultrasound on liquid–liquid reactions have been reported in the literature. Most of

them benefit from the emulsifying effect of ultrasound and the resulting high interfacial area. In some cases, a phase-transfer catalyst became unnecessary. Most reactions are between immiscible aqueous and organic liquid phases.

The decomposition of organic halides is faster due to the better mass transfer from the organic phase into the aqueous phase, where secondary radical reactions with hydroxyl radicals lead to unspecific degradation. Examples of ester hydrolysis, substitution reactions, and addition reactions in two phase liquid–liquid systems can be found in [7].

Ultrasonic Mixing. Nonreactive mixtures of liquids can be mixed by ultrasound. High shear velocities and oscillating and transient bubbles create very intense local conditions, which are employed for homogenization or emulsification. Many industrial processes in the food and drug industries use the liquid whistle, a long-known device which uses a high-velocity liquid stream impacting a steel blade to create vibrations. Typical applications are the homogenization of water-oil mixtures for the production of soups, sauces or the rapid mixing of fruit juices from concentrates [3].

Emulsification. The main mechanisms for emulsification applying ultrasound are pressure gradients, cavitation and the resonance of capillary waves. The pressure gradient, Δp_{dr}, in a cavitation-free fluid has to overcome the capillary pressure, Δp_{cap}, of the droplet with the radius R_{dr} and the interfacial tension σ_L.

$$\Delta p_{dr} = \left.\frac{dp}{dy}\right|_{max} \cdot 2 \cdot R_{dr}$$
$$\Delta p_{cap} = \frac{2 \cdot \sigma_L}{R_{dr}} \tag{25}$$

Further, the frequency f_{us} of the ultrasonic field determines the deformation time t_{def}, which is available to perform the droplet breakage.

$$t_{def} = \frac{\pi}{f_{us}} \tag{26}$$

The critical deformation time [47-49] amounts to

$$t_{def} = \frac{\eta_{L,2}}{\sigma - \Delta p_{cap}} \tag{27}$$

where $\eta_{L,2}$ is the dynamic viscosity of the second, dispersed liquid. In the case of drop breakage, the tension σ is equal to the external pressure gradient Δp_{dr}. The effect of the pressure gardient is quite small below 100 kHz. With increasing frequency, the pressure gradient Δp_{dr} increases and with it the possible deformation of the droplet.

Droplets formed from the collapse of waves have a diameter about the same size as the wavelength itself. Typical process parameters in emulsification lead to a wavelength of about 50 micron, which is about the size of droplets within a raw emulsion before sonication. Therefore the mechanism of collapse of waves is not the governing effect forming fine-disperse emulsions.

It is supposed that primarily cavitation provokes the dispersion of large droplets into smaller droplets forming a stable emulsion. The raw emulsion is a heterogeneous system, therefore the asymmetrical bubble oscillations and collapses in the vicinity of droplets lead to liquid microjets and shock waves. The microjets induce strong local friction forces and pressure gradients, which are supposed to be the governing effect in drop dispersion. These effects and their quantification are subject to actual research, because a multiplicity of the experimental results names cavitation as main effect in emulsification.

The process result for ultrasound emulsification can be plotted in a diagram of droplet diameter versus energy per volume. The curves for ultrasonic emulsification show the same behaviour as those for conventional emulsification equipment. The efficiency of ultrasound emulsification is higher in o/w-emulsions than in w/o-emulsions. This is due to the higher intensity of cavitation in the aqueous phase.

3.4. Phase-Transfer Catalysis

Alkylations are important reactions in heterocyclic chemistry and provide a simple means for introducing substituents. Phase-transfer catalysis (PTC) allows very fast and facile reactions when combined with sonication. The alkylation of indole and carbazole with alkyl and benzyl halides under liquid/solid PTC conditions in toluene with solid KOH gives higher yields and shorter reaction times than the stirred reaction [20]. Reaction times are shortened from several hours to less than one hour under ultrasound.

The preparation of azides from primary alkyl halides and aqueous sodium azide under PTC conditions is easier and cheaper under ultrasound and smaller amounts of PTC reagents can be used.

3.5. Sonoelectrochemistry

Deposition of Metals. Acoustic microstreaming and transient events can aid the deposition of metals in electroplating processes [27]. The very high mixing efficiency in cavitating sound fields is used to destroy the polarization barrier surrounding the electrode. Constant mechanical treatment by transient bubbles leads to surface hardening, less porosity, better brightness and to very good adhesive deposits for a variety of metals, including copper and gold.

Electro-Synthesis. Electrochemical methods are of widely recognized importance in the generation of intermediates which are difficult to prepare by other means [24], [28]. Problems arise due to mass transfer limitations, fouling of the electrode, or the evolution of gases. Applications in the Kolbe reaction and dechlorination of polychlorinated biphenyls can be found. Reductions of benzaldehyde and benzoquinone are reported in [29], in which a novel electrochemical reactor employs the

ultrasound source as one electrode for the reaction. The production of microemulsions and the dispersing effects of ultrasound are used where immiscible liquids have to be treated. Applications are found in wastewater treatment and other environmentally important processes. An effective removal of gases produced at an electrode can help to shift reversible reactions. Chlorine and hydrogen removal leads to very effective electrochemical cells. Transient bubbles and intense micromixing are responsible for the disintegration of diffusion layers, thus eliminating mass transfer limitations in electrochemical reactions. Cyclovoltammogrammic measurements of reversible redox reactions show very characteristic peak shapes in the silent case due to diffusion limitations. Under sonication, step responses are observed, and the underlying electrode kinetics can be measured without mass transfer limitations. Limiting currents which are ten times higher than in the silent reaction are common. Due to the profound influence of ultrasound on electrode kinetics, a change in the product spectrum of electrochemical reactions is sometimes observed.

[Top of Page]

4. Homogeneous Systems

4.1. Aqueous Liquids

The sonochemistry of water, often called sonolysis, is mainly determined by the production of radicals. Among the earliest observations in sonicated aqueous solutions was the liberation of molecular iodine from solutions of KI. The so-called Weissler reaction is one of the standard reactions for the chemical dosimetry of cavitating liquids. The primary step is the homolytic cleavage of water in the bubble. Saturating the water with tetrachloromethane facilitates the production of radicals:

$$H_2O \xrightarrow{)))} OH\bullet + H\bullet \qquad (28)$$

Hydrogen radicals react with water molecules to give further $OH^{\bullet}$ radicals and molecular hydrogen. The recombination of $OH^{\bullet}$ radicals at the bubble-liquid interface forms hydrogen peroxide. VON SONNTAG [30] estimated the $OH^{\bullet}$ concentration in the liquid boundary layer to be 1.2×10^{-2} mol/L. Hydroxyl radicals and chlorine radicals react with iodine to yield after recombination molecular iodine as a complex with I^-:

$$OH^{\bullet}/Cl^{\bullet} + I^- \rightarrow OH^-/Cl^- + I^{\bullet}$$

$$2I^{\bullet} + I^- \rightarrow I_3^- \qquad (29)$$

The existence of hydrated electrons under noble gases has been proposed by Margulis [6].

$$H^{\bullet} + OH^- \rightarrow H_2O + e_{aq}^- \qquad (30)$$

Volatile components in the water enter the cavitating bubble and are attacked by the $OH^{\bullet}$ radicals. Dissolved gases like nitrogen yield HNO_2, HNO_3, and smaller amounts of NH_3 and N_2O. Mixtures of N_2 and H_2 lead to the production of NH_3; mixtures of H_2 and CO lead to formaldehyde. A mixture of N_2 with CO, CH_4, or HCHO gives small amounts of various amino acids.

Organic components are attacked by $OH^{\bullet}$ and $H^{\bullet}$ radicals within the bubble or in the bulk liquid to give a wide range of secondary radical products. The irradiation of aqueous solutions of maleic acid with traces of Br_2 leads to a rapid isomerization to fumaric acid. The reaction is initiated by the cleavage of the bromide bond, the addition of the bromide radical to the double bond of maleic acid. Isomerization and subsequent liberation of bromide radicals lead to fumaric acid, which precipitates. The degradation of organic solutes in water is used in the wastewater treatment for removal of traces of halogenated aromatic and aliphatic compounds.

Inorganic compounds also undergo secondary radical reactions. Redox reactions with various ionic components are reported in [7].

4.2. Nonaqueous Liquids

Most nonaqueous liquids have a much higher vapor pressure than water, and this strongly cushions the transient bubble collapse. Therefore, early measurements that showed only very few sonochemical effects in water-free liquids are easily understood. Such liquids exhibit sonochemical effects such as bond cleavage only at low ambient temperatures. The sonolysis of alkanes [31], for example, yields nearly the same products (H_2, CH_4, 1-alkenes) as the high-temperature pyrolysis reaction. On irradiation halocarbons undergo homolytic halogen-carbon bond cleavage and give molecular chlorine and secondary radical products.

Another example for the preparation of organometallic complexes and the different product spectrum compared to thermolytic or photolytic pathways was presented by SUSLICK who sonicated iron pentacarbonyl in alkanes:

(31)

The products are decomposed to pyrophoric iron, when cavitation becomes too intense, and only solvents with higher vapor pressure and therefore less intense transient cavitation are suitable.

4.3. Polymers and Macromolecules

The preparation and degradation of long chain molecules under sonication is the result of two effects: creation of radicals by mainly mechanical chain cleavage of polymers and initiation of radical reactions by generation of primary radicals in transient bubbles.

Depolymerization. Early experiments with sonicated macromolecules revealed decreasing viscosity of the solutions. These changes can be attributed to a homolytic chain cleavage of the molecules. Drag forces acting on a dissolved polymer molecule are created in the vicinity of oscillating bubbles. High stresses are also created in shock waves from transient cavities. In dilute solutions, the polymer radicals react with solvent molecules to terminate the radical chain reaction. In concentrated solution, copolymerization and side chain branching occur. A lower limit for the molecular mass of the degraded polymer is observed in most cases. At a sufficiently small chain length, further degradation is stopped by the small drag forces acting on the molecule. The limiting molecular masses lie in the range of 10^4. The mechanical action of transient cavitation in polymer degradation becomes clear in the resulting molar mass distributions. Chains of higher mass are degraded more rapidly than those of lower mass. Degradation by ultrasound therefore leads to a narrower size distribution. Controlled depolymerization can be used to improve material properties such as mean polymer molecular mass, viscosity, and workability [3].

Polymerization. The creation of radicals in transient bubbles can be used to initiate radical polymerizations. Very high initial polymerization rates are observed at low temperatures for both pure monomers and monomers with initiators. Ultrasound produces a large number of radicals compared to traditional methods, and highly uniform size distributions are possible. With further sonication, depolymerization becomes increasingly important, and proper control of ultrasound parameters is necessary to achieve the desired polymer properties. The emulsification capabilities of ultrasound are utilized in suspension polymerization, where less surfactant is required and smaller size distributions are observed.

Copolymerization. The chain cleavage of polymers generates radicals which react with other reactants in the bulk. Concentrated polymer solutions (above 10 wt %) show side branching and copolymerization if two different polymers are present. Copolymerization of two polymers, for example, polystyrene and poly(methyl methacrylate), by ultrasound leads to random block and graft copolymers. In most cases the product is unfavorable, but the method can be a valuable tool for the preparation of mixtures from immiscible polymers. Copolymerization of a polymer in the presence of monomers leads to better defined block copolymers.

4.4. Sonoluminescence

Ultrasonic irradiation of liquids produces under certain instances light. This sonoluminescence is easily observed in water, ethylene glycol, and glycerin. In water, light emissions at 310 nm from excited $OH^{\bullet}$ radicals and a broad band in the entire continuum are observed. Whether this broad emission is due to black body radiation or excited molecules is still unknown. Other liquids show emission spectra from different excited species. Alkanes show a strong band in the C_2^* region (the Swan band). The production of C_2H_2 from sonicated alkanes provides evidence for excited species in the transient cavity. Sonochemically excited molecules and their reactions in the high-temperature region of bubbles seem to be responsible for the flame-chemistry-like behavior of sonoluminescence.

Single Bubble Sonoluminescence. In single-bubble sonoluminescence (SBSL) experiments [5], a bubble is trapped in a pressure antinode of a standing wave field. At a sufficiently high sound pressure of slightly above 0.1 MPa, this bubble oscillates stably but with high wall velocities and emits light in the UV/Vis region. Higher sound pressures cause a transient behavior and disappearance of the bubble. SBSL is used to examine the various parameters that influence bubble motion and sonochemical sonoluminescence efficiency.

Multi-Bubble Sonoluminescence. In extended sound fields, several types of bubbles, (e.g., stable and transient), are present. These create different temperatures and pressures inside oscillating bubbles and should therefore show a broader spectrum than in SBSL. MBSL experiments with aqueous solutions of various alcohols revealed a scavenging effect of these compounds. Sonoluminescence was suppressed at higher concentrations of alcohol, and this was interpreted in terms of reaction with $OH^{\bullet}$ and $H^{\bullet}$ radicals produced by homolytic water cleavage. Electrolytes can alter the SL spectrum. Emissions of neutral metal atoms indicate the possibility of metal vapor inside the cavities, which show the characteristic bands in the compression cycle when temperatures are high enough to vaporize the metals [5]. The mechanism of the generation of metal atoms from ionic metallic atoms by cavitation is still unknown, but theories about the reduction of the metal ion at the hot solid – liquid interface of a transient cavity seem plausible.

[Top of Page]

5. Equipment

5.1. Transducer Technology

Ultrasound transducers create the high frequency vibrations which are submitted into the liquid.

Two major types of transducers are used for liquids: liquid-driven and electromechanical.

Liquid-driven transducers are widely used in the food industry for mixing and homogenization. The principle is that of a liquid whistle. Liquid is pumped through a small orifice and hits a blade. The sudden pressure drop in the orifice causes hydrodynamic cavitation, and the blade generates ultrasonic vibrations and cavitation. A precise design of flow velocities, orifice and blade are necessary to allow high liquid throughputs with optimum mixing conditions.

Electromechanical transducers are based on piezoelectric or magnetostrictive principles. Both transducers need a high frequency generator for electrical supply. Magnetostrictive transducers are made of ferromagnetic material which alters its geometrical dimensions in an applied magnetic field. Bars or rods made of ferrite ceramics achieve high driving forces below 100 kHz. The major drawback of magnetostrictive transducers are their poor efficiency and rather broad frequency behavior.

Piezoelectric materials change their dimensions when charges are applied to opposite faces. These transducers have a natural resonance frequency at which the driving current produces the highest efficiency. Piezoelectric transducers are often made of barium titanate, lead metaniobate, and lead zirconate titanate ceramics and are supplied in most laboratory and industrial equipment. Operation at highest efficiency is responsible for the fixed frequency of common ultrasonic systems and the reason for the difficulty in examining the influence of frequency on sonochemical effects. Modern piezoelectric transducers have a sandwich structure with two electrically opposed piezo ceramics between two metal blocks. The sandwich is clamped together to prevent mechanical damage due to stress in the ceramic. The transducer usually has a length of half a wavelength, operates in compression mode, and generates amplitudes of up to 20 µm [32]. Piezoelectric transducers are depicted schematically in Figure 7.

Figure 7. a) Schematic sketch of a piezoelectric ceramic with electrodes which changes its thickness d_e with applied charge; b) Transducer sandwich with two piezoceramics for low intensity devices; c) Transducer with booster and stepped horn

5.2. Reactors for Sonochemical Reactions

One of the major drawbacks in industrial applications of ultrasound is the complex scale-up procedure. Readily available laboratory equipment such as ultrasonic baths, high-intensity disintegrator horns, and cup horn reactors are used to measure sonochemical effects. All influencing parameters such as intensity, frequency, temperature, and vessel geometry must be the same for reproducible results. Critical ultrasonic parameters include the amplitude of the transducer, the ultrasonic intensity, the total power input, the specific power input per volume, the gas content, the local sound-energy distribution, and, in the case of heterogeneous reactions, the distribution of reactants. A successful scale-up must take these various factors into account.

5.2.1. *Laboratory Equipment*

Low-intensity applications can be tested in a commercial ultrasonic bath (Fig. 8 a). Several transducers are mounted at the bottom of a bath and are driven with the same frequency. A complicated standing wave field is created, and the sonochemical effects depend on the location of the samples in the bath and the filling height.

Probe systems are applicable in high intensity experiments at up to ca. 100 W/cm^2 at frequencies below 100 kHz. Multiplication of the transducer amplitude by a booster and a horn make it possible to increase the amplitude by a factor of around 10. The vibrating tip of the horn is dipped into the liquid and creates intense cavitation in its vicinity (Fig. 8 b). Ultrasound is attenuated rapidly, and only a few centimeters are sonochemically active. Such probes generate a large amount of streaming, so external stirring is unnecessary. The intense cavitation causes erosion of the tip and therefore contamination of pure liquids. A variant of the probe system is the so-called cup-horn reactor with indirect sonication of a submersed sample through a sound-transmitting liquid, which can be cooled (Fig. 8 c).

Figure 8. Laboratory equipment for sonochemical experiments a) Ultrasonic bath; b) direct-immersion horn; c) Cup-horn reactor

5.2.2. *Large-Scale Equipment*

Liquid-whistle reactors (Fig. 9 a) are still very important in homogenization and mixing processes. High throughput, stable operation, and the ability to adapt to existing flow systems are only some of the advantages of this system [23]. Fruit juices, sauces, and mayonnaise are prepared in large quantities. This low-intensity equipment can not be used where more severe cavitation is required. Other low-intensity devices are reactors with external or submersed plate or rod transducers (Fig. 9 b, c) which are easily fitted to existing tanks of several cubic meters and allow a fast scale-up. Tube transducers can also be retrofitted to existing plants. All low-intensity devices transmit sound energy over large volumes with dimensions greater than the liquid wavelength. The typical power input is roughly 50 W per transducer at a frequency of 20 kHz and a diameter of

6 cm.

Figure 9. Low-intensity ultrasonic devices a) Liquid whistle; b) Tank reactor with wall-mounted transducers; c) Tank with submersed plate transducer; d) Tank with submersed rod transducer

High-intensity devices are applicable when the dimensions of the sonicated volume are equal to or smaller than the liquid wavelength. Probe systems can be used in small flow cells, which consist of several probes in series and can be retrofitted to existing plant. Gap reactors force liquids through the most active zone of a probe transducer. The power input per transducer reaches 2 kW with a radiating surface diameter of up to 10 cm.

Figure 10. Tube reactors a) Conical, hexagonal, and heptagonal reactors; b) Raiganis tube reactor with axial cooling; c) Sodeva sonitube with stepped horn and resonant collar; d) Branson sonochemical reactor with coupling fluid

Another way to introduce high-intensity ultrasound are tube reactors (Fig. 10). Transducers are mounted on the outer wall of a tube and create intense cavitation in the center. Variants of this principle include the cylindrical pipe reactor; the cylindrical reactor with core cooling; hexagonal and heptagonal tubes, which allow easier transducer mounting on their plane walls; the Branson sonochemical reactor with a coupling fluid between the horn and the reactor wall; and the Sodeva sonitube with a stepped horn and a resonant collar mounted on a cylindrical pipe.

Gap reactors (Fig. 11 a) consist of a high-intensity stepped horn which is coupled with a small gap of a few millimeters. The fluid is driven through the gap and is treated by high-intensity ultrasound for a very short time. Particle size reduction and mixing are the main applications for these devices.

The reverbatory ultrasonic reactor (Fig. 11 b) consists of two opposing plates with a gap of a few centimeters. The use of two different frequencies (20 and 15 kHz) is very effective in particle size reduction. Other high-intensity systems are implemented in a tube (Fig. 11 c, d). Radial oscillations are responsible for the transmission of sound into the liquid. Examples for these devices are the Martin-Walter push-pull reactor and the Telsonic rod-reactor.

Figure 11. a) Gap reactor; b) Lewis reverbatory ultrasonic reactor; c) Martin Walter push-pull reactor; d) Telsonic rod reactor

5.3. Mapping of Sonochemical Reactors

The mapping of sononochemical reactors shows the intensity distribution of the pressure field within the reactor volume. This knowledge is essential, because most sonochemical effects need a minimum intensity of the ultrasound field. In the remaining reactor volume, where the sound intensity is too low, undesired side reactions can occur, decreasing the product quality.

5.3.1. *Hydrophone*

The hydrophone records the frequence of pressure changes within the sonicated liquid phase. With the help of a Fourier transformation (FFT), the frequence spectrum is calculated from the raw data. The response of the hydrophone clearly shows whether cavitation ocurrs or undisturbed pressure waves run through the liquid. Non-cavitating liquids only show the hydrophone response at the driving frequency of sonication. Cavitaton additionally generates overtones, thus the FFT shows peaks at multiples of the driving frequency [50].

The hydrophone has to be protected from cavitation effects. These lead to decalibration or even worse to destruction of the sensor. Because of its quite small size, the hydrophone can be moved within the sonicated vessel to measure the local intensity and frequency of the acoustic field.

5.3.2. *Thermocouples*

The measuring principle uses the heat generation during the absorption of ultrasound. The sensor consists of two thermocouples [48], [51]; one is covered with an absorbing material like silicon rubber. The temperature difference in the steady state of operation can directly quantify the intensity of the ultrasound field. Because of the quite small construction of thermocouples, an excellent local resolution of the sound field is possible. The precision of the measurement is negatively influenced by cavitation, which changes the frequency of the acoustic field.

5.3.3. *Optical Methods – Bubble Dynamics*

By applying of optical methods, it is possible to localize the cavitation zone; the optical properties of the liquid change when gas bubbles are created [48]. With the help of a high-speed video system, it is possible to track gas bubbles within or near the cavitation zone. This method can be used to localize secondary vortices in the flow field outside the cavitation center.

More precise is the particle image velocimetry (PIV) [52]. This method takes several photographs of the trajectories of small tracer particles in suspension in a thin plane of fluid, which is illuminated with a spread laser beam. The two components of the velocity vector in the illuminated plane are given by the traces left on the pictures during the exposure time. In cavitating liquids, the cavitation bubbles themselves can serve as tracers.

5.3.4. *The Weissler Reaction [52]*

Bubble cavitation leads in aqueous liquids to the formation of reactive radicals such as OH·, H·, and H_2O_2. These short-lived species are capable of inducing secondary oxidation and reduction reactions. For example, iodide (KI) can be sonochemically oxidized to triiodide by OH· radicals or H_2O_2. From aqueous solutions containing chlorocarbons, Cl· and Cl_2 are also liberated in high yields, which increases the rates of iodide oxidation. The rate of triiodide formation is easily monitored spectrophotometrically. This so-called Weissler reaction is still one standard dosimeter for sonochemical reactions because of its exclusive direct reaction to cavitation and its independence to temperature or sheer effects.

Because of mixing effects in the liquid, the Weissler reaction gives an integral value of the cavitation intensity. If the local intensity is of interest, the KI solution has to be separated from the main liquid in a special container, which is acoustically coupled to the liquid in the reactor [50].

Abstract

Spray forming is an advanced process route to produce near-net-shaped preforms from metallic materials. As it combines the main advantages of the classical processes of metal casting and powder metallurgy, its products are characterized by extraordinary material properties. Since the 1970s this process has been developed and it is now in its commercialization state in several applications, e.g., in the automotive and aerospace industry. Though essentially a metallurgical process, understanding and optimization is based on principles of process and chemical engineering. This is reflected by means of the three process stages as: melt atomization, spray evolution, and droplet deposition. In this contribution these three subprocesses will be introduced and basic features of the process will be discussed

1. Background and Potential of the Process

Spray forming is a metallurgical process which combines the main advantages of the classical processes of:

– Casting: near net shape manufacturing of large preforms, and
– Powder metallurgy: homogeneous grain structure for small components.

A schematic of a typical spray forming plant is shown in Figure 1. The metal melt is poured from the crucible into the tundish and flows into

© 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.b24_b02.pub2

the atomization region where it is usually disintegrated by impinging high-energy inert gas jets. In the resulting spray cone, the molten metal droplets partly solidify and are accelerated towards the substrate, where they are compacted to a solid preform (deposit).

Figure 1. Schematic of the spray-forming process

The idea of spray forming was developed in the late 1960s by Singer [1] at the University of Swansea in Wales. In the 1970s spray forming was further developed for the production of thin metal sheets directly from the melt, as an alternative to the conventional metallurgical route of casting and subsequent forming of large slabs. Also in Wales, members of Singer's group commercialized the spray forming process by founding the company Osprey Metals Ltd. in Neath. Since then, research groups worldwide have taken an active part in the research and development of the fundamentals and potential applications of spray forming [2 – 8]. At present, numerous industrial applications of spray-formed materials are successfully at the market. Application areas are within automotive and aerospace, electronics and manufacturing. A review of the applications of spray forming is given in [9, 10].

The materials that are commonly used for production of semifinished products by spray forming are:

- Aluminum-, copper- and iron-base metals and alloys which are difficult to cast because they tend to segregate
- Superalloys (e.g., on nickel-base) and titanium
- Particle-reinforced metal-matrix composites (MMCs)

The main geometries which are produced by spray forming are shown in Figure 2.

Sheets are manufactured by scanning (oscillating) the atomizer or by using linear-slit nozzles to spread the spray cone over a certain area and by spraying onto a substrate in linear motion. Metal sheets are of great commercial interest, e.g., in the aluminum industry, but are difficult to spray form up to now due to processing problems.

Tubes and *rings* are produced by scanning the atomizer or by stationary spraying onto a tubular or cylindrical substrate. The core is drilled out or remains in the form to give a two-layered product (with different properties on the inside and the outside). Spray-formed tubes are used in the chemical industry, and spray-formed rings will have applications in turbines and propulsion units (aeronautics and astronautics).

Billets are presently the most common geometry manufactured by spray forming. Cylindrical billets are commonly used as preforms for a subsequent extrusion process. Billets are manufactured by off-center spraying at an angle of inclination onto a rotating cylindrical substrate, which is withdrawn during the process, generally in the vertical direction for a standing billet, but sometimes in the horizontal direction to produce a lying billet with larger dimensions. To increase the production rate and throughput, sometimes two atomization units are used simultaneously [11 – 13]. Spray-formed billets are presently produced up to a diameter of approximately 0.5 m and up to a height of 2 m. Applications are in automotive industries (aluminum) or in superconductors (copper).

Figure 2. Spray forming of different preform geometries

The main advantages and properties of spray-formed products and materials are:

- Absence of macro-segregations
- Homogeneous, equiaxial grain structure
- Increased strength
- Increased elongation
- Low oxygen content
- Better hot workability

The specific advantages of different spray-formed materials, the properties of spray-formed near net shaped products, and the state of the art in the industrial application of the process are documented in the periodical international user conferences on spray forming (ICSF) [14 – 16], in the publication series of the scientific contributions on spray forming in the special research program at the University of Bremen [17 – 23], and in the Proceedings of the International Confereneces on Spray Deposition and Melt Atomization SDMA [24, 25], including contributions to fundamentals and applications in:

- Copper-base materials [26]
- Aluminum-base materials [27, 28]
- Ferrous alloys and steels [29 – 31]
- Titanium and ceramic-free superalloys [32]
- Compound materials and MMCs [33]
- Lightweight materials (e.g., magnesium) [34]

From a process engineering viewpoint, the sprayforming process can be divided into several sequential unit operations. Different setups and ways of describing and combining these fundamental process steps can be found in [4, 35 – 37].

Starting point of an analysis is the subdivision of the spray-forming process into three main stages [38], as shown in Figure 3.

1) Preparation of the melt and atomization: This stage includes the preparation of the alloy and the delivery and the disintegration of the fluid from the continuous melt flow to a spray with a droplet size distribution.
2) Particle transport in the spray cone: The behavior and development of the spray cone are described by the multiphase flow of metal droplets/particles and gas, and by momentum and heat transfer within and between phases.
3) Impact and deposition of droplets: The impact of the droplets, their compaction to give a deposit, the establishing of the so-called mixing layer (or mushy zone) at the deposit surface, and the behavior of the product are involved in this stage.

Figure 3. Three process stages of spray forming

The possibilities for an optimized, automated spray-forming process are discussed in [39]. Starting from the division into three main stages, one can relate the geometrical and operational parameters of the process to those stages which must be visualized, measured, and controlled. Changing the operational parameters of the process results in a complex behavior of the coupled stages of the spray-forming process and, ultimately, a quite different quality of the sprayed product. The control of the droplet size spectrum in the spray cone is the most important control parameter in a spray-forming process. The key parameter for online process control is regulation of the gas to metal flowrate ratio (GMR) by control of the gas mass flow rate of the atomizer (assuming constant thermal conditions). The aim is to influence the atomization process and therefore directly influence the coupled multiphase transport and solidification of particles in the spray cone. The disturbing variable of this control process is mainly the fluctuation of the metal melt flow rate in operation (due to changing melt properties during the process or stochastic influences), which must be continuously measured [40] and controlled during operation to give a closed control loop.

2. Atomization

Of the various atomization principles and devices which are used for disintegration of molten metals [41, 42] for powder generation and

Figure 4. Close-coupled and free-fall atomizers for metal powder production and spray forming

spray-forming applications, twin-fluid atomization with inert gases is best suited [43], because:

- High mass flow rates of melt can be atomized to increase the yield
- High heat transfer rates from the droplets can be realized
- High momentum transfer rates can be achieved to accelerate the droplets
- Low oxidation rates of the material in the spray process are obtained

Common to all twin-fluid atomizers for molten metal disintegration are a vertical flow of a cylindrical melt jet from the tundish in the direction of gravity and a parallel or inclined, coaxial gas jet with high kinetic energy. Two kinds of atomizers can be distinguished (Fig. 4): the free-fall configuration and the close-coupled (confined) atomizer. The efficiency of the close-coupled atomizer is higher (in terms of smaller droplet sizes) compared to the free-fall atomizer, due to the closer spacing of the gas jets and the melt outlet. However, the close-coupled atomizer has the higher potential for melt freezing at the nozzle outlet, because the temperatures of the expanding pressurized atomizer gas are usually below 0 °C and high cooling rates of the melt flow result at the tip of the tundish. Freezing is a major problem, because the spray forming is a batch process, and freezing often occurs in the start-up phase.

Another advantage of the free-fall atomizer is the possibility of mechanically scanning or oscillating the separate atomizer gas ring. This gives the process operator an additional possibility for influencing the droplet mass flux distribution in the spray cone. This important parameter can normally be changed only over a narrow range for a given process by changing the atomizer gas pressure, which simultaneously changes the overall behavior of the spray (e.g., by changing the droplet sizes).

Figure 5. Two-stage atomization (primary and secondary gas flow) and particle recirculation in the free-fall atomizer

The analysis of the atomization process requires knowledge of the flow field of the atomizer gas in the vicinity of the twin-fluid nozzle [44 – 47]. The gas flow field is responsible for the melt-disintegration process, but also has a guidance and shielding function with respect to the initial behavior and distribution of the spray cone. These two requirements can be achieved by means of a two-stage free-fall atomizer (Fig. 5), in which a primary gas flow emerging close to the melt outlet guides the melt flow into the atomization region, while a secondary gas flow field emerging from the lower gas ring impinges on the central melt stream and disintegrates the melt [48]. Due to the inclination of the secondary (atomization) gas flow, recirculation areas are frequently observed in the vicinity of the nozzle. Individual particles entering these zones may be transported vertically upwards, in opposite direction to the main gas flow, as can be seen in Figure 5, in which a photograph of part of the atomization area is mounted. When these particles hit the nozzle body close to the melt outlet

Figure 6. Comparison of simulation and experiment for twin-fluid atomization [49]

Figure 7. Comparison of simulation and experiment for twin-fluid atomization [49]

they may stick there, resulting in a severe disturbance of the process and in extreme cases, complete plugging of the nozzle.

Figure 6 compares a numerical simulation of the (subsonic, $Ma \leq 1$) gas flow in the vicinity of nozzle (vector diagram) with the atomization of a model fluid (water) in a free-fall atomizer [49]. The atomization gas pressure in this case is $p_2 = 1.89$ bar abs.; therefore, the gas exit condition is critical with an exit velocity equal to the velocity of sound ($Ma = 1$) but without any shock cells in front of the nozzle. In this analysis, no primary gas flow is applied ($p_1 = 0$). The secondary atomizer gas flow exits the gas ring with an inclination angle of $10\,^\circ$ and hits the centerline of the atomizer just above the theoretical atomization point (the intersection point of the atomizer centerline with the gas jet exit line). The deviation is due to the contraction of the atomizer gas flow. Ambient gas is entrained and accelerated into the inner flow field. This gas stream flows through the gap between the

main body of the nozzle and the lower atomizer gas ring into the inner area of the flow field. In the middle of the inner area, a large recirculating vortex flow can be seen, the border of which is indicated by a solid line in Figure 6. Here, upward vertical gas velocities of up to 50 m/s are attained. Individual particles entering this area of upward flowing gas are accelerated towards the main body of the nozzle and the melt exit. This is also observed in the experimental model atomization process: individual droplets which are transported vertically upwards can be seen above the atomization region.

An appropriate nozzle configuration and condition for a failsafe operation of the atomization nozzle in spray forming of molten metals needs:

- A smooth outer nozzle contour, which exactly follows the streamline structure to prevent flow separation at sharp nozzle edges
- Location of the primary gas outlet as close as possible to the melt flow
- A suitable gap width between the main body of the nozzle and atomizer gas ring
- A minimum amount of primary gas flow, in combination with the atomizer gas pressure

The calculated gas flow field in an optimized free-fall nozzle configuration is shown in Figure 7 for an atomization gas pressure of p_2 = 1.89 bar abs. and a primary gas pressure of p_1 = 1.4 bar abs. [49]. Here, the gas flow field in the vicinity of the nozzle has no recirculation zone. The experimental model atomization shows the successful prevention of droplet recirculations for this nozzle.

This underlines the importance of the primary gas flow. Also the geometric contour of the atomizer gas exit configuration must be analyzed. In a conventional free-fall atomizer, the gas flow exit configuration is a line of individual cylindrical holes without inner contour on a common circumference of the atomizer gas ring. The atomization gas pressure is typically between 3 and 8 bar abs. ($Ma > 1$). Therefore, the individual gas jets exit the atomization nozzle in a choked (underexpanded) condition with a local pressure above ambient pressure. This flow generally tends to form a series of shock waves and expansion cells that cause energy losses [50]. An investigation of the transonic atomizer gas flow behavior in the vicinity of the nozzle shows that the use of contoured gas nozzles (Laval type) to give supersonic gas outlet conditions ($Ma > 1$), significantly augments the kinetic energy in the atomization region [45]. This behavior is shown in Figure 8, for the simulated flow field of a free-fall atomizer operated at p_2 = 5 bar abs. The left half of the figure is the result for an underexpanded gas flow, and the right half for a fully expanded supersonic gas flow field.

Figure 8. Numerical simulation of gas flow in the nozzle vicinity of a free-fall atomizer; underexpanded (left) and idealy expanded (right) [45]

The gas flow field disintegrates the melt by transfer of axial and tangential momentum to its surface, resulting in the formation of droplets and the spray cone. One of the main parameters describing the spray is the droplet size distribution. It is commonly described by an empirical correlation [52] for the mass median particle diameter as:

$$d_\mathrm{p} = d_\mathrm{l} K_\mathrm{lub} \left(\frac{\nu_\mathrm{l}}{\nu_\mathrm{g}} \frac{1}{We} \{1 + \frac{\dot{m}_\mathrm{l}}{\dot{m}_\mathrm{g}}\} \right)^{0.5} \tag{1}$$

where K_lub is an empirical factor which mainly depends on the atomizer geometry. The Weber number

$$We = \frac{\varrho_\mathrm{l} u_\mathrm{max}^2 d_\mathrm{l}}{\sigma_\mathrm{l}} \tag{2}$$

is calculated by means of the melt properties and the maximum gas velocity u_max of the atomizer gas flow field. The maximum gas velocity in the atomization region has been measured and correlated for the typical free-fall arrangement shown in Figure 7 as [45]:

$$u_\mathrm{max} = 645.25\, \dot{m}_\mathrm{g}^{0.585} \tag{3}$$

where the gas mass flow rate is related to the absolute atomization gas pressure in the choked flow regime by:

$$\dot{m}_g = 0.685\,\mu_f A\,\frac{p_0}{\sqrt{RT_0}} \tag{4}$$

where the friction coefficient μ_f is 0.84. The result of a sample calculation of the resulting mean droplet sizes for various atomized pure metals is shown in Figure 9.

Figure 9. Particle diameter of melt droplets from twin-fluid atomization

A more detailed break-up model for description of melt-jet fragmentation needs the description of several subsequent stages of the atomization process as:

- the gas velocity field,
- the primary interaction of gas and melt jet and its break-up,
- the secondary interaction of gas and melt fragments and droplet break-up,
- drop collision effects as coalescence or fragmentation,
- the coupling of dispersed phase and continuous phase.

An uncoupled numerical computation of the atomization process and spray development is described here where the most relevant process parameters for atomization as the gas-to-melt mass flow ratio GMR are taken into account. In the computation, every droplet/particle in the flow field (no particle parcels) is tracked. The local acceleration of the droplet, the effect of turbulence, the secondary break-up, and the cooling of the molten droplet are taken into account. Drop collision effects are neglected.

Figure 10. Stability curves for metal jet, $d_0 = 4$ mm, $u_0 = 2$ m/s, $u_{gas} = 100$ m/s (A), Sn, $u_{gas} = 50$ m/s (B) [55]

Theoretical investigations of the primary liquid jet break-up in a gaseous environment are based on the (linear) stability analysis of the coupled gas and liquid flow fields. For an inviscid flow, this is the classical Kelvin-Helmholtz instability as derived e.g. in [53, 54] for the description of the stimulation of the primary disintegration process in the area of small wavelengths within coaxial atomization of liquids.

Comparison of different modes of stability for a jet of molten metal in a coaxial gas flow has been discussed in [55]. Typical results for perturbation growth rates of different metal melts are shown in Figure 10 in the upper part and for the four basic modes of instability (n = 0, 1, 2 and 3) for a tin melt jet in Figure 10 in the lower part. The influence of material properties on melt-jet stability is mainly due to the surface tension, increasing from tin ($\sigma = 0.544$ N/m) via copper ($\sigma = 1.31$ N/m) to steel ($\sigma =$

1.83 N/m). Increasing values for surface tension result in decreasing Weber numbers, which result in smaller amplitudes of the growth rate. In the same way the dominant wavelength of jet disintegration increases. Higher-order instability modes are important. Maximum growth rates are observed for the symmetric mode m = 0, but the asymmetric growth mode m = 1 has almost identical growth rates while higher modes show somewhat smaller growth rates.

The secondary break-up process generally is defined as the fragmentation of ligaments into droplets, including the successive break-up of droplets into smaller droplets [56, 57]. In gas atomization of melts in free-fall atomizers, usually the melt mass flow rate (typically 0.05 ... 0.5 kg/s) is in the order of the gas mass flow rate. The describing parameter of the fragmentation process, the GMR, is about 1 to 2 and the atomization zone is characterized by:

- high acceleration of particles,
- high cooling rates and
- high particle bulk density.

At moderate superheats for metallic melts, the effect of viscosity is small. Different mechanisms of the break-up of molten metallic droplets were described by Krzeczkowski [58]. He distinguished between four break-up mechanisms:

- bag break-up for $We = 12 \ldots 20$,
- umbrella break-up for $We = 20 \ldots 35$,
- mixed break-up (of bag and umbrella type) for $We = 35 \ldots 70$, and
- ligament break-up for $We > 70$.

Below the limit of $We_{\mathrm{crit}} = 12$ a droplet may still be deformed, but remain stable as a single droplet. By observing the region of melt ligaments secondary break-up with high speed imaging, it was found, especially for large particles with a diameter above 200 µm, that the particles typically are nonspherical, but having an irregular shape. These droplets may still be in the state of deformation or spheroidization on break-up.

The break-up modes classification of Pilch and Erdmann [59] includes a description of break-up mechanism for high Weber numbers above $We > 350$. For very small Weber numbers, $We < 12$, a droplet may still break up into two equally sized droplets under certain conditions. According to this classification, Samenfink et al. [60] distinguished basically three mechanisms:

- bag break-up for $We = 12 \ldots 20$,
- multimode break-up for $We = 20 \ldots 70$, and
- shear break-up for $We > 70$.

For liquids of various viscosities, Hsiang and Faeth [61] derived an empirical correlation between the Sauter mean diameter and the Ohnesorge and Weber numbers. The initial droplet diameter before break-up is d_{part}.

$$\frac{d_{32}}{d_{\mathrm{part}}} = 1.5\,\mathrm{Oh}^{0.2}\,\mathrm{We}_{\mathrm{gas}}^{-0.25} \tag{5}$$

Typical values of liquids are in between $Oh^{0.2}$ $We_{\mathrm{gas}}{}^{-0.25} = 0.05 \ldots 0.4$, where metallic melts are also in this range. In case of shear break-up, the resulting droplets with new diameter d are root normal distributed as:

$$f(d) = \frac{\sqrt{\frac{d}{d_{50.3}}}}{2\sqrt{2\pi}\sigma d} e^{-\frac{1}{2}\left[\frac{\sqrt{\frac{d}{d_{50.3}}}-\mu}{\sigma}\right]^2}, \quad \text{where } \mu=1,\ \sigma=0.238 \tag{6}$$

$$d_{50,3} = 1.2\, d_{32} \tag{7}$$

This distribution has been applied by Schmehl [62] also for the bag- and multimode break-up regimes.

The Taylor analogy break-up model (TAB) [63] describes the resulting droplet diameter after secondary disintegration, where the Sauter mean diameter d_{32} for very low and high Weber numbers results in:

$$\frac{d_{32}}{d_{\mathrm{part}}} = \frac{3}{7} \text{ for } We \to We_{\mathrm{crit}} \text{ and } \frac{d_{32}}{d_{\mathrm{part}}} = \frac{12}{\rho_{\mathrm{gas}} u_{\mathrm{rel}}^2} \text{ for } We \to \infty \tag{8}$$

While the empirical model is applied in this work, the lower limit can be used at the critical point.

The dynamics of the break-up process also depend on the aerodynamic Weber number. In a simplified model, the molten droplet deforms to a disk and then breaks up into new droplets. A characteristic break-up time t^* is defined as:

$$t^* = \frac{d_{\mathrm{part}}}{u_{\mathrm{rel}}} \sqrt{\frac{\rho_{\mathrm{liquid}}}{\rho_{\mathrm{gas}}}}. \tag{9}$$

The deformation time is $t_{\mathrm{def}} = 1.6\, t^*$ due to [61]. The time needed for break-up is t_{breakup}

$= k \cdot t^*$, whereas k is an empirical constant depending on the break-up regime. The break-up time has been measured or estimated [63 – 68]. Compared to the break-up time, the spheroidization time is small, $t_{\text{spheroidisation}} = 0.88\ \mu_{\text{liquid}}\ d_{\text{part}}/\sigma << t_{\text{breakup}}$. For example, a molten steel droplet of $d_{\text{part}} = 100$ µm needs about 250 ns to spheroidize, which is many times faster than any possible break-up time. So it is assumed that new particles immediately after break-up are spherical.

Figure 11. Instantaneous particle distribution for a spray atomized at 0.4 MPa, droplets coloring by specific enthalpy [55]

Figure 11 shows a typical instantaneous spatial distribution of the droplets in the spray. In the initial region of droplet production, a tendency to clustering of droplets is to be seen. Due to the sequential fragmentation of larger melt fragments that have been separated from the liquid jet, droplets are segregated in droplets clusters first. Further downstream these clusters are mixed to a more homogeneous droplet distribution mainly due to turbulence effects. The individual liquid elements and droplets are coloured by means of its specific enthalpy, where the cooling rate of droplets is illustrated.

The basic influence of the increased GMR and hence the nozzle pressure for a steel jet at 150 °C superheat atomized with nitrogen is shown in Figure 12. The resulting particle distribution is shifted from big to smaller particles for increasing nozzle distance.

Figure 12. Size distribution at the distance x of the gas nozzle of an atomized steel jet, relative nozzle pressure $p_{\text{gas}} = 0.25$ MPa (A) and $p_{\text{gas}} = 0.4$ MPa (B) [55]

3. Spraying

The physical behavior of the spray cone is the key process for the development of a high-quality sprayed product [69, 70]. In the spray, a complex two-phase flow situation containing gas and particles/droplets occurs. The high-speed gas loses its momentum by accelerating the droplets. Due to the heat transfer from the droplets, the gas undergoes intense heating in the zone close to the atomizer. The droplets are accelerated and partly solidify during their flight. The mixture of different stages of droplet solid-

ification is believed to give the optimum conditions for producing a homogeneous preform. The largest droplets will reach the point of impingement in the liquid state. Due to their high mass they are still in the process of solidification. The medium-sized droplets are in a semisolid or mushy state, while the smallest particles are already fully solidified when they hit the deposit or substrate.

Measurement of droplet size and velocity distribution within molten metal sprays can be found in [71 – 74]. Continuous information on droplet behavior in the spray is obtained by numerical simulations [37]. Here, a model of the complete dispersed two-phase flow situation including momentum and heat coupling, is used to describe and analyze the complex spray cone behavior. Euler – Lagrange [75 – 77] or Euler – Euler modeling is used [78, 79] for multiphase flow analysis. In both types of multiphase flow model, the gaseous phase is described as a continuum (Eulerian approach) by means of conservation equations for momentum, mass, and energy. In an Euler – Euler model the dispersed phase is also described as a quasi-continuum, based on the same conservation equations, averaging the particle properties over a finite volume. In an Euler – Lagrange model of the dispersed phase, individual particles (or particle parcels) are tracked through the flow field. Depending on the material used and alloy composition, different solidification models have to be included in the simulation.

A high-speed-pyrometry system may be used for monitoring of the spray forming process [80]. The use of high-speed pyrometry in a two-phase flow under spray forming conditions enables the determination of temperature, velocity and size of in-flight particles without any influence on the measuring environment and on the spray itself. This measurement device consists of three main components as illustrated in Figure 13: a) a sensing head located near the spray cone collecting the thermal radiation emitted from the hot particles, b) the detection cabinet containing the optical components and photodetectors, and c) a computer equipped with the required digitizing and computing boards. The sensing head is aimed perpendicular to the spray cone collecting the light emitted by in flight particles. The collected light is imaged on the end of the optical fiber bundle. The core fiber is covered by a two-slit photomask. Each slit width and the distance between the slits is designed for a specific measurement range. The detection system for the central fiber is a high-speed, two-color pyrometer where the light is focused through a dichronic mirror onto two photodetectors. The signals are statistically compiled, displayed, and saved. Light from a particle traveling in the sensors focal plane enters the central fiber only when at least part of its image is located within one of the masks two slits. The characteristic signature of a particle crossing the sensors focal point is a two-peak signal representing 100 %, 0 %, and again 100 % of its radiation within the corresponding detector bandwidth. The shape of

Figure 13. System components of an in-flight high-speed particle pyrometer [73]

the measured two-peak signal depends on and changes with the particle velocity, temperature, diameter, and trajectory. The particle velocity, v_p, is computed from measuring the time interval between the two peaks. The particle temperature, T_p, is obtained from the ratio of signal intensities from each detector according to Planck's law and assuming that emissivity of particle surface is the same at both wavelengths ($\varepsilon(\lambda_1) = \varepsilon(\lambda_2)$):

$$T_p = \frac{c_2\,(\lambda_1 - \lambda_2)}{\lambda_1 \cdot \lambda_2} \cdot \left[\frac{1}{\ln R + 5 \cdot \ln \frac{\lambda_1}{\lambda_2}} \right] \tag{10}$$

where c_2 is the second radiation constant and R is defined as the energy ratio of $E(\lambda_1)/E(\lambda_2)$. Both energies are calculated through the time integral of the two-peak signal normalized by the velocity. Using Planck's law by taking into consideration that melted particles are spherical or at least very close to be, one can derive the diameter of a particle d_p from

$$d_p = \sqrt{\frac{E\,(\lambda_i)}{c_3 \cdot \varepsilon\,(\lambda_i)}} = \sqrt{\frac{E\,(\lambda_i)}{d_c}} \tag{11}$$

where i represents 1 or 2 and c_3 is the third radiation constant. Since $\varepsilon(\lambda_i)$ is extremely difficult to define, the calculation system includes a coefficient d_c, which includes both c_3 and $\varepsilon(\lambda_i)$. For a new material with a thermal history emissivity $\varepsilon(\lambda_i)$, and thus d_c, is unknown at the beginning of the experiment. In order to obtain precise d_p values, one must follow, for each different material, a calibration procedure.

Spray forming of high carbon steel (100Cr6, containing 1.35 to 1.6 % chromium) exhibit the influence of different spraying conditions on the particles thermal and kinetic state. On the spray center line the axial distance is varied in three steps as $z = 150$ mm, $z = 200$ mm, and $z = 325$ mm from the nozzle. The melt superheat of $\Delta T = 150\,°C$ and the atomizing gas pressure of $p_g = 2.5$ bar were constant. Figure 14 demonstrates the measured particle temperature versus the cumulative number distribution (counts in %) with increasing axial distance. It is important to point out that even in the nearest position of the spray cone ($z = 150$ mm) most of the particles in spray forming process have a temperature beneath the state of phase change (for the used high-carbon steel the liquidus temperature is $T_l = 1450\,°C$, and the solidus temperature is $T_s = 1300\,°C$, the temperature range of solidification will be identified in the temperature plots by a grey bar). As to be seen from Figure 15, the particle velocity increases slightly with increasing measurement position indicating that on average, the droplets were continuing to accelerate at these axial distances. The increase of particle diameter illustrated in Figure 16 occurs because of the higher radial dispersion of smaller particles in comparison to that of larger particles with more mass inertia. The general flow direction and turbulence of the gas carries them away from the centre to outer parts of the spray cone with increasing distance from the atomization nozzle.

Figure 14. Change in particle temperature with variation of the measurements position (grey area = solidification temperature range) [73]

Figure 15. Change in particle velocity through variation of the measurements position [73]

Figure 16. Change in particle diameter with variation of the measurements position [73]

Figure 17. Scheme of backscatter PDA optical setup for spray forming application [74]

Phase-Doppler-Anemometry (PDA) is another suitable process measurement technique to detect size and velocity of spherical particles with smooth surfaces simultaneously in multiphase flows. However, sprayed droplets and particles within liquid metal atomization do not fulfill these requirements. Due to high cooling rates in flight some particles are partially or completely solidified exhibiting a rough surface due to dendritic solidification. This surface roughness causes noisy and weak signal response within light scattering. In order to overcome this problem, as well as to tackle difficulties resulting from the hostile environment inside the spray chamber during spray forming, an adaptation and modification of the common PDA technique is necessary. A detailed description of conventional PDA techniques is given in [81 – 83]. Specifically the signal processing had to be modified because of the poor signal quality [84, 85]. The optical part of the PDA is realized in direct backscattering direction, as illustrated in Figure 17. Consequently, a compact moveable PDA is used where only a single window in the spray chamber for optical access is needed. The ability to move the measurement volume in vertical as well as in horizontal direction during one spray forming run allows the investigation of different measuring locations in the spray.

Using this modified PDA, the spray cone resulting from the atomization of the liquid metal jet can be investigated with regard to different process parameters, e.g., gas flow, melt temperature, and measurement position in the spray cone [86].

Using this modified PDA, not only particle size and velocity in the two-phase flow can be measured but also the local mass flux can be determined. The PDA results have been verified by comparing this data to results received via sieve

analysis of collected particles as illustrated in Figure 18. Measurements carried out with usage of a scanning atomizer, resulting in a movement of the spray cone relative to the (fixed) interference volume, demonstrates the sensitivity of the employed measurement technique [74, 87]. In order to generate definite deposit geometries by spray forming, in most cases the movement of the atomizer is necessary. Varying the position of the measurement volume relating to the substrate/deposit, the mass distribution in dependence on the local position above the deposit can be estimated.

Figure 18. The cumulated mass versus particle size obtained by using PDA and sieve analysis, respectively [87]

By extending the PDA technique to an on-line measurement system, even process analysis very close to real time becomes possible and the PDA can be used to monitor the spray forming process [88].

For this, the Fourier based signal processing has to be realized via hardware, i.e., a special PDA signal processor has been developed, the use of which allows the data evaluation in only a couple of seconds. The signal flow is as follows:

1) The analog PDA signal is converted to a digital one,
2) the signal is computed in a digital signal processor (DSP) considering the introduced Fourier analysis,
3) the resulting diameter and velocity distributions can be used for both monitoring the atomization process and controlling the process,
4) for controlling the process an adjustment signal is created by comparing the actual value of the mean particle diameter (or the mean particle velocity) to the corresponding set value,
5) the digital adjustment signal is converted to an analog signal, the quantity of which is influencing the valve for the atomization gas pressure.

In its most simplified form, a gas control loop consists of the PDA measurement unit, the regulating valve and the control unit allowing the automatic adjustment of the mean particle velocity or diameter by varying the atomization gas pressure. Analyzing the atomization process taking place during spray forming the significant influence of atomization gas pressure on particle properties can be shown [89, 92]. Since particle diameter and velocity are essential to heat and mass transfer, among others these process parameters are defining the thermal conditions of the impacting particles and with it the properties of the spray-formed material like microstructure, grain size, and chemical homogeneity. Thus, the aim is to monitor and to control the spray forming process on the basis of the mean particle diameter and velocity, respectively. In order to investigate the control loop and the on-line PDA, respectively, in this section sharp variations in gas pressure are realized, purpose of which is not to produce a high-graded deposit but to examine the temporal behavior of the atomization process and in addition that of the on-line PDA unit.

Figure 19 summarizes the on-line measured mean particle velocity and the corresponding atomization pressure versus duration of one spray forming run. In case of particle velocity the actual as well as the desired value are shown, i.e., using the closed control loop a definite particle velocity $v_{1,0,\mathrm{set}}$ is proposed and the required adjustment of the current particle velocity $v_{1,0,\mathrm{act}}$ by varying the atomization gas pressure p_{g} is observed. The graphs agree with the well-known correlation of particle velocity and gas pressure. Therefore, with an increasing gas speed the immediate increase of particle velocity can be made out using PDA. By contrast, some more time is needed to adjust the actual particle velocity. In Figure 19 time intervals of $\Delta t = 27$ s and $\Delta t = 35$ s are needed to realize the necessary adaptation of the current particle velocity to the set value. Nevertheless, time consumption for ad-

justment is of that scale that influencing control throughout a current process is realizable.

Figure 19. Automatic control of the particle velocity [74]

The second PDA measurable particle property is the diameter. Within the scope of verifying the ability of diameter control the set-value of the mean particle diameter $d_{1,0,\mathrm{set}}$ is placed several times far from the actual value $d_{1,0,\mathrm{act}}$ (corresponding to Figure 20) bringing modifications of the gas pressure as large as possible. It can be seen that the corresponding mean diameter of the metal droplets is following in the expected way, even if only a slight change in the average diameter is noticeable and a straggling conditional on fluctuations of both the measurement technique and the process itself are unavoidable. Using PDA as an on-line measurement system and adapting the on-line PDA to a closed control loop for the atomization gas enables the measurement and influencing of the metal disintegration process. Hence, process control very close to real time becomes possible. Subsequently, well-aimed variations in the atomization result can be created and measured by varying the atomization gas pressure within the scope of automatic control operations.

As an example of a modeling result for the spray cone behaviour, Figures 21 and 22 show the behavior of different droplet classes on the centerline of a spray of molten steel particles atomized with nitrogen [75]. The boundary conditions include an atomizer pre-pressure of p_2 = 3 bar abs., a gas to metal flow rate (GMR) of 1.25 and a droplet size distribution of log-normal type with a mass median droplet size of 133 μm. The axial velocity distribution on the spray cone centerline for gas and particles with different diameters is illustrated in Figure 21. The gas velocity far upstream of the atomization area is unaffected by the particles. Close to and in the atomization region, the gas velocity decreases due to the momentum transfer for acceleration of the droplets. Afterwards, the gas velocity increases again because of intense heating of the gas and the resulting thermal expansion and also due to the entrainmaint of momentum from the edge of the spray cone. The maximum gas velocity occurs at a distance of ca. 330 mm from the nozzle. Afterwards, the gas velocity decreases due to spreading of the spray cone. Close to the point of spray cone impingement onto the deposit/substrate, the axial gas velocity rapidly slows to zero. Particles are accelerated in the atomization region and further downstream. In the main region of the spray cone, particle velocities of the larger particles remain almost constant.

Figure 20. Automatic control of the particle diameter [74]

Figure 21. Gas and particle velocities on the spray cone centerline [75]

Figure 22. Gas and particle temperature on the spray cone centerline [75]

The gas temperature in the atomization region reaches values of up to 1200 K (Fig. 22) [75]. Further downstream, the local gas temperature on the centerline decreases, but heat transfer from the particles still occurs, due to the spreading of the spray and mixing with colder ambient gas. Particles are assumed to be preheated to 125 K above the solidification temperature at the point of atomization. After cooling to the solidification temperature, the phase change occurs inside the particles and the latent heat of the particles is released, whereby the particle tem-

perature remains constant. When the latent heat content of the droplets has been removed, the particles cool further. From these calculations it can be seen, that particles bigger than 210 µm are still in the state of phase change when they impact the substrate/deposit.

The mass flux distribution in the spray cone is directly related to the shape of the sprayed deposit. For varying deposit shapes, either the atomizer and/or the substrate can be moved. For a stationary atomizer, the radial profile of the mass flux distribution in the spray cone can be described as an exponential function by:

$$\dot{m}_{\mathrm{spray}}(r) = \dot{m}_{\mathrm{max}} \exp\left(\ln 0.5 \left|\frac{r}{r_{0.5}}\right|^{k_1}\right) \tag{12}$$

The maximum mass flux is always found on the spray cone centerline and $r_{0.5}$ is the half-width of the mass flux profile (see Fig. 23). The exponential factor is correlated as k_1 = 1.3 [90, 91] and k_1 = 1.124 [92] for steel atomization. The half-width of the mass flux profile is proportional to the maximum mass flux value:

$$\dot{m}_{\mathrm{max}}(x) \sim \frac{1}{r_{0.5}^2(x)} \tag{13}$$

For calculating the mass flux distribution at each position within the spray cone, a single calibrating measurement at one point on the centerline in combination with the mass flux correlation is sufficient.

Figure 23. Principle of mass flux distribution profile

In a similar way, the thermal energy flux (enthalpy flux) within the spray may be detected and described [93, 94].

4. Deposition

Droplet deformation during droplet/particle impingement onto the substrate/deposit is described in [95 – 98]. A possible reason for micropore formation in spray forming and thermal spray processes based on the combined deformation and solidification of droplets is given in [99, 100]. Here it is shown that ejection of the liquid material over a rapidly solidified base layer of the splat may result in a gap or pore.

The impinging droplets transport mass, momentum and thermal energy into the top layer of the deposit [93]. The compacted mass is not identical to the theoretical impinging mass from the spray because

- Smaller droplets of low inertia follow the gas streamlines and are deflected
- Droplets may bounce off or splash and secondary droplets may not be incorporated in the deposit
- Particles with high momentum may tear off parts of the already compacted mushy top layer

These particles contribute to the overspray. The difference between the mass flux value in the spray cone and the compacted mass is described by the deposition efficiency:

$$k(\vec{x},t) = \frac{\dot{m}_{\mathrm{compac}}(\vec{x},t)}{\dot{m}_{\mathrm{spray}}(\vec{x})} \leq 1 \tag{14}$$

The deposition efficiency is a function in space and time and is mainly proportional to:

- The thermal state of the impingement surface
- The momentum, temperature and state of solidification of the impinging droplets

The deposition efficiency for spray forming of Gaussian shaped deposits (produced with a stationary atomizer, spraying on a stationary cylindrical substrate) from steel is given by [92]:

$$k(T_{\mathrm{p}}, f_{\mathrm{L}}, I_{\mathrm{p}}) = C_4 \left[C_1 + C_2 \left(\frac{T_{\mathrm{p}}}{T_{\mathrm{L}}}\right)^{C_3}\right] f_{\mathrm{L}}^{C_5} I_{\mathrm{p}}^{C_6} \tag{15}$$

where the coefficients C_1 to C_6 are:

C_1	0.422	C_4	0.489
C_2	0.800	C_5	0.249
C_3	30.48	C_6	– 0.062

The main influencing parameter for the deposition efficiency is the temperature of the droplets at impact (here normalized with respect to the liquidus temperature).

During spraying, the deposit grows continuously and releases its heat by conduction to the substrate and convection and radiation to the surrounding gas.

If the particles are not fully solidified prior to impact on the substrate, which is a fundamental condition for the compaction of particles to a homogeneous preform, a solidification front must exist at some point in the deposit. To calculate the spatial and temporal temperature distribution in the deposit and substrate, numerical methods have been used [6, 101 – 104], because of the difficulty of temperature measurement in the deposit. These models consider the deposition rate, but are limited to one- or two-dimensional configurations. In an extended approach, a more accurate and more general formulation of the problem is given and solved in [105, 106].

By numerical modeling, a description of the cooling process of metals during flight, deposition and further cooling periods in spray forming (which are of major importance for the understanding, control and optimization of the process) can be obtained and analyzed. The quality of spray-formed products in terms of homogeneity and improved material properties is directly controlled by the cooling rate of particles in the spray cone and the further cooling behavior of the resulting preform. The solidification and cooling behavior of the material directly depends on operational parameters.

A result of a thermal calculation in the deposit and substrate during spray forming of a Gaussian shaped steel deposit is shown in Figures 24 and 25 [105, 107]. The transient contour of a growing deposit and the calculated surface temperature is shown in Figure 24 after 15 and 30 s spray time. Then the spray process ends, and the cooling period begins. Therefore, the deposit shape does not change any further, but the surface temperature decreases due to cooling from the gas flow. In Figure 25 the temperature distribution in the central plane inside the deposit and underlying substrate is illustrated at the same time intervals as in Figure 24. The calculated temperature behavior shows a temperature difference immediately at the interface between deposit and substrate. Here, due to a residual oxide layer and pore formation in the first compacted material layers, a heat transfer resistance results and decreases the heat transfer from the deposit into the substrate [4]. After 60 s total time, a hot-spot area inside the deposit can be identified. The continued cooling of the gas flow results in a colder shell around a hot core. This area is extremely problematic with respect to grain coarsening and (for spray forming of solid preforms) hot shortness. Temperature simulations of the heat balance in the deposit and substrate can reveal possibilities for avoiding hot spots.

Figure 24. Surface temperature of spray-formed Gaussian-shaped deposit

Problems in spray forming may arise from remaining gas pores in the preform. These may occur, e.g., because of gas entrapment (too hot spray conditions) or unsufficient liquid content in the spray (too cold spray conditions) The possible formation of macro- and micropores in spray-formed deposits has been investigated within modeling of the spray solidifying on an arbitrary surface within a geometry simulation by Djuric et al. [108, 109]. As also has been

pointed out, e.g., by Cai and Lavernia [110], the presence of some remaining porosity is inevitable in spray-formed materials. Typically zero or low porosity (< 1 %) is found in the largest region in the core of spray-formed preforms, but the porosity level may increase up to 10 % within the surface area of the preform. From a quality point of view, porosity in spray deposited materials yields two types of problems. First, material properties may degrade because of the presence of pores. Second, secondary working (such as extrusion, rolling, forging, and HIPing) is necessary to achieve full density, which in turn limits the suitability of spray forming as a near-net shape manufacturing process. Consequently, research and modeling efforts have been initiated in spray forming to better understand the formation mechanisms of porosity formation and determine ways to decrease the porosity level either by adjusting the process parameters or by exploring alternative approaches.

The total porosity in an as-deposited material in spray forming can be described as the sum of:

- porosity from gas entrapment,
- interstitial porosity,
- porosity associated with shrinkage during solidification.

Among these mechanisms, interstitial porosity has been reported to play the most important role in porosity formation during spray forming, particularly when spraying thin geometries like bands and strips or tube clads. Considering that the formation of interstitial porosity is due to the lack of liquid to fill the overlapped particle interstices, whereas solidification porosity is significant when too much liquid is present in the spray upon impingement, interstitial porosity and solidification porosity may be treated as two mutually exclusive occurrences. Consequently, in a modeling approach, when interstitial porosity is predominant, solidification porosity is ignored (and vice versa). In a first modeling approach [110], the gas entrapment porosity has been neglected. The model starts to describe the consolidation mechanism in two stages. In the first stage, solidified droplets impinge on the deposition surface and form a random-dense particle packing. Within the second stage, liquid droplets first impinge on the resultant particle packing and finally solidify. If the volume of liquid, once solidified, is smaller than that of voids in the particle packing, porosity is assumed to be dominated by interstitial porosity, whereas the solidification shrinkage is neglected. On the other hand, if the volume of liquid, once solidified, is more than that corresponding to voids, porosity is assumed to be controlled by solidification of the liquid left and interstitial porosity is neglected – solidification porosity is dominating. For this model, the particle size distribution in the spray has been assumed as of log-normal type, the median particle diameter has been adopted from Lubanska's formula (Eq. 1), and the standard deviation of the drop size distribution has been taken from empirical metal atomization data [111].

Figure 25. Temperature inside Gaussian-shaped deposit and substrate during spray forming

The porosity model has been applied to spray forming of an Al-4-wt% Cu alloy, atomized

by nitrogen. The main process parameters have been varied as the atomization gas pressure in a range from 1 to 10 MPa, the melt flow rate between 0.001 and 0.02 kg/s, and the melt superheat from 50 to 250 K. The temperature of the atomization gas has been assumed as constant. A typical result of the simulation is shown in Figure 26. Here, the variation of porosity with deposition distance for an atomization gas pressure of 1.2 MPa, a melt flow rate of 0.01 kg/s and varying melt superheats is illustrated. The porosity level exhibits a V-shaped variation with deposition distance, reflecting both types of porosity reasons, the solidification and the interstitial porosity. For small deposition distances the spray is too hot and solidification porosity results. As deposition distance increases, porosity decreases continuously to such a point where minimum porosity is achieved. Beyond this point, porosity increases almost linearly with increasing deposition distance. Here, the spray conditions become too cold and the porosity is caused be interstitial effects. As an example, for a melt superheat of 100 K, porosity is 5 % at deposition distance of 0.1 m. The point corresponding to a minimum porosity in this case is at a deposition distance of 0.36 m. For increasing melt superheat, the minimum porosity is achieved at longer deposition distances.

Figure 26. Porosity as a function of deposition distance for an atomization gas pressure of 1.2 MPa and a melt flow rate of 0.01 kg/s for Al-4Cu [110]

The variation of other process parameters, as the atomization gas pressure and also the melt flow rate, result in principle in similar V-shaped porosity curves as for varying the deposition distance. Based on these results, optimum combinations of processing parameters during spray forming may be identified. A porosity coefficient may be introduced [110] to identify dominant mechanisms in the different porosity formation regimes. In addition to porosity, other process constrains, such as microstructure as well as process economy, have to be taken into consideration for finding a set of suitable spray forming process conditions.

The model study on porosity formation in spray forming [110] has only the spray conditions taken into account. For further model developments, as main influencing parameter for porosity, also the state of the deposit surface has to be taken into account. This may be achieved mainly in terms of deposit of the surface temperature, which severely affects the porosity as well as the particle sticking efficiency [112].

Figure 27. Local porosity in as-sprayed IN718 rings on cold substrate (marked as Whi-96) and this study (run 354), atomizer gas is argon [113]

The porosity at the bottom of spray-formed products may be successfully decreased by preheating the substrate surface. This has been demonstrated in [113] for spray forming of rings from superalloys IN718 and U720. Within this process the melt was superheated (app. 150 K above liquidus temperature) in the crucible. Subsequently, the melt (150 kg) was pulled into the preheated tundish and left the nozzle where it is atomized. A rotating cylindrical shaped sub-

Figure 28. Porosity of spray-formed IN718 before and after HIP [113]

strate was preheated to app. 1150 °C by an induction coil from the inside of the rotating substrate (rotation frequency 1.2 Hz). By using the preheated substrate the base porosity of the deposited ring structure has been drastically decreased as illustrated in Figure 27 in a comparison to a sprayed ring using a cold substrate. After subsequent HIPing of the sprayed rings, the overall material porosity may be decreased below 0.1 % in most parts of the deposit (Fig. 28).

5. Integral Modeling

Modeling and simulation of the spray forming process is an essential tool for process understanding and development [37, 114, 115]. Integral spray forming models especially for the thermal behaviour in spray forming have been derived by Bergmann [116], Minisandram et al. [117], and Pedersen [118 – 120]. Connection of various submodels is performed for transient-temperature material behaviour, from melt superheating in the tundish to room temperature in the preform via cooling and solidification. By inclusion of a tundish melt flow and thermal model in a first stage, employment of the local separation method for spray properties averaged temperatures and solid fractions for the particle mass on the centre line of the spray is done in a second stage. The time axis is shown in terms of the mass averaged mean residence time of the particle mass. By combination of these data with the calculated temporal cooling and solidification distributions of a fixed volume element inside the deposit, one yields the mean thermal history of the material at a specified location in the deposit.

The transient thermal and solidification distributions are shown in Figures 29 and 30. Results are illustrated separately for the three different modeling areas (with different time scales): a) melt flow in the tundish, b) particle cooling in the spray, c) growth and cooling of the deposit. The process conditions used are for a steel spray forming experiment for production of a Gaussian shaped deposit.

From top of the tundish (upper melt surface) to the exit of the tundish in the atomization nozzle, the melt is cooled by approx 20 K (for an initial melt temperature of $T_L = 1933$ K). Solid fraction of the melt does not change as the melt stays fully liquid ($f_s = 0$). In total, the mean residence time of the melt in the tundish is 51.6 s for an exit diameter of $d_{exit} = 4$ mm of the tundish and a surface height of $h = 0.25$ m of the melt in the tundish (determining the melt mass flow rate). A velocity profile within the melt flow develops in the tundish with highest velocity values on the centre line.

In the spray flow, mainly convective heat transfer to the gas cools the melt droplets. Until the spray impingement onto the substrate ($z =$

Figure 29. Integral thermal spray forming model: Temperature evolution from tundish to deposition [116]

Figure 30. Integral thermal spray forming model: Solid fraction evolution from tundish to deposition [116]

0.6 m; $s = 0.47$ m) the mean residence or flight time of the particles in the spray is 11 ms. In this time the melt material is cooled down by $\Delta T =$ 260 K ($T_m = 1650$ K) corresponding to a mean cooling rate of 2.4 10^4 K/s. Hereby the mean solid fraction in the spray increases to $f_s = 0.71$.

Because of thermal diffusion and the release of latent heat inside the deposit, the material temperature directly after compaction at first increases by further increasing the local solid fraction. For the discussed parameter setting the temperature increase is approx 90 K. After complete solidification of the volume element under investigation ($f_s = 1$) the temperature will decrease again by a cooling velocity of approx. 2 to 3 K/s.

Abstract

The article contains sections titled:

1. Introduction
2. Synthesis
2.1. Network Formation and Structure
2.1.1. Inorganic Aerogels
2.1.1.1. SiO_2 Aerogels
2.1.1.2. Metal Oxide Aerogels
2.1.2. Inorganic/Organic Hybrid Aerogels
2.1.3. Organic Aerogels
2.2. Drying Methods
2.2.1. Supercritical Drying
2.2.1.1. Drying in Organic Solvents
2.2.1.2. Supercritical Drying with CO_2
2.2.2. Freeze Drying
2.2.3. Ambient Pressure Drying
2.3. Modification of Aerogels after Drying
3. Properties
3.1. Structural Properties
3.2. Physical and Chemical Properties
3.2.1. Optical Properties
3.2.2. Mechanical and Acoustic Properties
3.2.3. Thermal Conductivity
3.2.4. Hydrophobicity
4. Applications
4.1. Çerenkov Detectors
4.2. Thermal Insulation
4.3. Catalysis
4.4. Application as Storage Media
4.5. Electrical and Electronic Applications
4.6. Acoustic and Mechanical Applications
4.7. Optical Applications
4.8. Other Applications
5. Future Perspectives

Aerogels are unique among solid materials. They have extremely low densities (up to 95 % of their volume is air), large open pores, and a high inner surface area. This combination of properties results in interesting physical properties, e.g., for silica aerogels extremely low thermal conductivities and low sound velocities are combined with optical transparency. Aerogels are typically prepared via wet chemical processes, such as sol – gel processing, and thus their pore system is

initially filled with liquid. Only special drying techniques allow for exchange of the pore liquid against air while maintaining the filigrane solid framework. The most common drying technique is supercritical extraction, and sometimes chemical modification of the inner surface can be used to facilitate drying. The structure of the gel network, and thus the physical properties of aerogels, decisively depends on the choice of the precursors and the chemical reaction parameters for preparing the gels. Therefore, the later materials properties can be deliberately designed in the starting reaction solution.

[Top of Page]

1. Introduction [1-11], [12-14]

Aerogels are highly porous solid materials with extremely low densities (bulk densities 0.004 – 0.500 g/cm^3), large, open pores, and high specific surface areas. This results in interesting physical properties, such as extremely low thermal conductivity and low sound velocity, combined with high optical transparency. Aerogels have been differently defined:

1. All materials prepared from wet gels by supercritical drying were called aerogels, irrespective of their structural properties. With the development of new drying techniques this definition is no longer appropriate.
2. Materials in which the typical pore structure and network are largely maintained when the pore liquid of a gel is replaced by air are called aerogels (this definition is used in this article). However, it is not always clear to what extent the structure is maintained.

Materials are porous if they contain cavities, channels, or interstices that are deeper than they are wide. The pores may be regularly arranged, as in molecular sieves such as zeolites (⟶ Zeolites). However, the more common situation is an irregular pore structure. The physical properties of a porous solid and its reactivity are effectively influenced by the type, shape, and size of the pores. Some technical terms are defined in Table 1.

The unique materials properties of aerogels result from the special arrangement of their solid network, which is schematically shown in Figure 1 for an SiO_2 aerogel [16]. The structures of aerogels are characterized by readily accessible, cylindrical, branched mesopores. Aerogels can be obtained as monoliths, granulates, or powders.

Table 1. Definition of terms for porous solids

Term	Explanation
Porosity of a solid	ratio of the total pore volume to the volume of the particles or powder
Pore shape	ink bottle, cylindrical, funnel, slit-shaped
Accessibility of the pores	closed, blind, through pores
Pore size and dominating transport mechanisms [15]	*micropores:* < 2 nm, activated transport
	mesopores: 2 – 50 nm, Knudsen diffusion, surface diffusion along the pore walls, capillary transport
	macropores: > 50 nm, molecular diffusion
Density	skeletal density: density of the solid network
	bulk density: mass per total volume (= solid phase + closed pores + open pores)

[Top of Page]

2. Synthesis

The network and hence the pore structure of gels is formed by the condensation of small (polymeric or colloidal) primary particles with a diameter of 1 – 3 nm. Their generation and aggregation is controlled by chemical processes, usually the sol – gel process [17-24]. In principle, the structures of all covalently bonded gels lie between those of colloidal gels (colloidal primary particles) and polymeric gels (polymeric primary particles), which constitute the two extremes with regard to both the microstructure and the resulting properties (Figure 2).

Figure 2. Two-dimensional structures of aerogels a) Colloidal; b) Polymeric; c) With a rough surface (see Section SiO_2 Aerogels) (Reprinted from [50] with permission of the Materials Research Society)

In a *sol*, particles with diameters in the range of 1 – 1000 nm are dispersed in a liquid. A *gel* consists of a sponge-like, three-dimensional solid network whose pores are filled with another substance, usually a liquid. When gels are prepared by hydrolysis and condensation of metal or metalloid alkoxides or other hydrolyzable metal compounds (via the sol stage), the pore liquid mainly consists of water and/or alcohol. The resulting “wet” gels are therefore called aquagels, hydrogels, or alcogels. *Aerogels* are obtained when the pore liquid is replaced by air without decisively altering the network structure or the volume of the gel body. *Cryogels* are obtained when the pore liquid is removed by freeze drying. A *xerogel* is formed by conventional drying of the wet gels, that is, by increasing the temperature or decreasing the pressure with concomitant large shrinkage (and mostly destruction) of the initially uniform gel body (Figure 3). The shrinkage of a gel body upon evaporation of the pore liquid is caused by capillary forces acting on the pore walls as the liquid retreats into the gel body. This results in the collapse of the filigree, highly porous inorganic networks of the aquagels or alcogels. Therefore, other drying methods must be used to prepare aerogels (Section Drying Methods).

Figure 3. Shrinkage upon drying of a wet gel body to give an aerogel (top) and to give a xerogel (bottom) as a powder (a) or as monolith (b)

2.1. Network Formation and Structure

Highly porous three-dimensional gel networks can be obtained for inorganic, inorganic/organic, and purely organic systems under controlled conditions although the solids content is typically only 1 – 15 vol %.

In colloidal gels, dense colloidal particles are interconnected like a string of pearls (Figure 2a). In polymer gels, linear or branched polymer chains are formed by condensation of small clusters (Figure 2b). In the sol – gel literature and in this article, the term cluster does not mean metal clusters, as is usual in chemistry, but instead the primary oligomeric species formed during sol – gel processing. Their structure can be chainlike, cyclic, or three-dimensional. There are several theoretical models for the aggregation of the clusters to three-dimensional networks [17], [25]. Each aerogel has its own structural characteristics because the microstructure strongly depends on the preparation conditions.

Aerogel networks are usually formed from colloidal particles. There are two principal possibilities for the formation of gels:

- Solid gels are dissolved (peptized) and the sols thus obtained (colloids) are reaggregated under different conditions.
- Sol particles are formed by chemical reactions from molecular precursors. Most aerogel syntheses follow this route. For example, the reaction of metal or metalloid alkoxide groups (M–OR) with water results in the formation of hydroxyl groups (M–OH), which can then condense to form M–O–M units.

The production of inorganic and inorganic/organic aerogels is shown schematically in Figure 4. Some parameters by means of which the sol – gel process and therefore the properties of the resulting aerogels can be influenced and varied are also listed. Organic aerogels are produced similarly.

Figure 4. General scheme for the preparation of aerogels by sol – gel processing and some typical parameters for variation

The solvent plays an important role in sol – gel processes. It not only serves to homogenize the precursors in the initial stage, but also strongly influences the particle- and network-forming reactions due to its polarity and viscosity. In the preparation of aerogels it has an additional function, as shown in Figure 4. Since gelation results in only a marginal change in volume, and the drying process during aerogel production is performed (by definition) such that shrinkage is minimal, the volume of the aerogel body (and hence its density) is determined by the volume of the reaction solution. Therefore, the density of aerogels is simply modified by varying the precursor concentration in the starting solution.

The sol – gel transition (gel point) is reached when a continuous network is formed. However, the chemical reactions are not finished at this point. First, the pore liquid initially is a sol, that is, it contains condensable particles or even monomers,

which slowly condense onto the existing network. Second, neighboring M–OH or M–OR groups can undergo condensation reactions (aging), because the gel network is still very flexible. Furthermore, hydrolysis and condensation reactions are in principle reversible. Therefore, mass is dissolved from thermodynamically unfavorable regions. The solutes condense in thermodynamically more favorable regions, especially in pores, crevices, particle necks, etc. (Ostwald ripening). This process results in the reduction of the net curvature, the disappearance of small particles, and the filling of small pores. Aging and ripening increase the stiffness of the gels (Fig. 4). Controlled aging is therefore an important aspect for the reproducible preparation of aerogels.

2.1.1. *Inorganic Aerogels*

2.1.1.1. *SiO_2 Aerogels*

The term SiO_2 gel (analogously for other gels) is only used to characterize the type of inorganic skeleton. The SiO_2 gels and the corresponding aerogels often have the composition $SiO_x(OH)_y$ or, if they are prepared from alkoxides, $SiO_x(OH)_y(OR)_z$, where the values of *y* and *z* can be (but need not be) rather high.

Most laboratory preparations of silica aerogels use tetraalkoxysilanes $Si(OR)_4$ as the silica source. The pore liquid of the gels formed after addition of a defined amount of water (Eq. 1) then mainly consists of the alcohol used as solvent and that produced by the hydrolysis reaction.

$$Si(OR)_4 + H_2O/ROH \rightarrow [SiO_2 \cdot H_2O/ROH]$$

The chemical reactions during sol – gel processing of alkoxysilanes can be formally described by three equations (Eq. 2). Hydrolysis reactions take place in parallel with condensation reactions during all steps of the sol – gel process. Therefore, all intermediate species still contain Si-OR and/or Si-OH groups.

$$\begin{array}{lcll} \equiv Si{-}OR + H_2O & \xrightleftharpoons{\text{acid or base}} & \equiv Si{-}OH + ROH & \text{Hydrolysis} \\ \equiv Si{-}OH + HO{-}Si\equiv & \rightleftharpoons & \equiv Si{-}O{-}Si\equiv + H_2O & \\ \equiv Si{-}OR + HO{-}Si\equiv & \rightleftharpoons & \equiv Si{-}O{-}Si\equiv + ROH & \text{Condensation} \end{array} \quad (2)$$

Parameters which influence the hydrolysis and condensation reactions and whose deliberate variation are used for “materials design” are shown in Figure 4. A variety of physicochemical measurements and some computer simulations were performed to determine the influence of these parameters on network formation of SiO_2 aerogels [7-11], [25-31]. Kinetic models for the growth of gel networks were postulated on the basis of small-angle X-ray scattering (SAXS) data [32], [33]. Two of the most important models are shown in Figure 5.

Figure 5. Dependence of the hydrolysis and condensation reaction on pH, and derived kinetic growth models of gel structures. RLCA = reaction limited cluster aggregation, RLMC = reaction limited monomer cluster growth (after [32], [25])

The kind of inorganic network formed by the condensation reactions not only depends on the absolute rates of the individual reactions but also on the relative rate of hydrolysis and condensation reactions [34], [35]. Acidic conditions (pH 2 – 5) favor hydrolysis, and condensation is the rate-determining step. A great number of monomers or small oligomers with reactive Si–OH groups are simultaneously formed. Under these conditions, reactions at terminal silicon atoms are favored, and chains with few branches are formed. This results in polymerlike networks with small pores. This process is called reaction limited cluster aggregation (RLCA).

Hydrolysis is the rate-determining step under basic conditions, which favor reaction at central silicon atoms of an oligomer. The resulting network has a particulate character with large particles and large pores (“colloidal” gels). Hydrolyzed species are immediately consumed because of the faster condensation reaction. Condensation of clusters with each other is relatively unfavorable [17]. Therefore, the clusters mainly grow by the condensation of monomers. This process is called reaction limited monomer cluster growth (RLMC) or Eden growth [36]. It would ideally result in uniformly dense structures. However, for tetraalkoxysilanes this simple model must be somewhat modified. Not all the four branching points are equal because only partially hydrolyzed $Si(OR)_{4-x}(OH)_x$ is initially formed from $Si(OR)_4$. Therefore, unchanged Si–OR groups are present at the growth front, which leads to inhomogeneous condensation, and rough structures are obtained (“poisoned” Eden growth; Fig. 2c).

Preparation of aerogels from polymeric gels is more difficult, because diffusion processes are strongly inhibited by the smaller pores. Complete removal of the pore liquid is therefore more difficult and results in a larger shrinkage during drying [37]. For this reason, silica aerogels are usually prepared by base-catalyzed reaction of tetramethoxysilane (TMOS) or tetraethoxysilane (TEOS), mostly with ammonia as the catalyst.

A modification of this procedure is to pre-hydrolyze $Si(OR)_4$ with a small amount of water under acidic conditions. This

results in the formation of small silicic acid clusters. In a second step, a defined amount of aqueous acid or base is added [38]. Networks formed by this two-step procedure have a structure similar to the RLCA model, that is, they have a polymeric character. The probable explanation is that the reactive clusters formed in the first step as structure forming units are responsible for the formation of the network, regardless of the kind of catalyst in the second step. The main difference caused by the kind of catalyst in the second step is the stiffness of the resulting network. Base catalysis in the second step results in stiffening, which stabilizes the gels. With this two-step procedure a more deliberate control of the microstructure and hence the particle and pore sizes of SiO_2 gels is possible. For example, while the density of aerogels made by one-step base- or acid-catalyzed reactions is restricted to the range of 0.030 – 0.300 g/cm^3, the production of an aerogel with a density of only 0.004 g/cm^3 was achieved by the two-step process [39], [40].

In a modification of the two-step procedure, oligomeric polyethoxysiloxanes of a certain size are prepared first from TEOS by addition of a defined amount of water. These defined oligomers were then used as precursors for sol – gel processing to form the three-dimensional network [41], [42].

For technical applications in which large amounts of aerogels are needed, alkoxysilanes are too expensive. Therefore, *water glass*, an aqueous sodium silicate solution, is used as the silica source. The sodium silicate solution is ion-exchanged, and the resulting silicic acid solution is gelled by changing the pH to acidic conditions [43], [44].

Silicic acid can also be transferred into an organic solvent in which condensation is then performed under acidic, neutral, or basic conditions. The resulting wet gels are also potentially suitable for the production of aerogels [45].

For the commercial production of Basogel, a two-step procedure was applied: The sodium silicate solution is mixed with sulfuric acid in the first step. Small hydrogel or aquagel droplets are formed by spraying. The metal salts are then extracted, and the water is replaced by an organic solvent [46]. The gel droplets are then supercritically dried.

The macroscopic properties of SiO_2 aerogels differ over a wide range, because of the differences in the structure of the primary particles and network formation. The structural data of SiO_2 aerogels listed in Table 2 therefore only serve as examples.

Table 2. Properties of SiO_2 aerogels

Property	Range	Typical value
Bulk density, g/cm^3	0.003 – 0.500	0.100
Skeletal density, g/cm^3	1.700 – 2.100	
Porosity, %	80 – 99.8	
Mean pore diameter, nm	20 – 150	
Specific surface area, m^2/g	100 – 1600 [47]	600
Refractive index	1.007 – 1.24	1.02
Thermal conductivity (in air, 300 K), W m^{-1} K^{-1}	0.017 – 0.021	0.020
Modulus of elasticity *E*, MPa	0.002 – 100	1
Sound velocity c_L, m/s	< 20 – 800	100
Acoustic impedance *Z*, kg m^{-2} s^{-1}		10^4

2.1.1.2. *Metal Oxide Aerogels*

The principles for network formation of nonsilicate inorganic gels are the same as for SiO_2 gels. Aqueous salt solutions or molecular precursors in organic solvents, again mostly alkoxides, can be employed for sol – gel processing.

Metal alkoxides are much more reactive towards water than alkoxysilanes. This is due to the lower electronegativity and higher Lewis acidity as well as the possibility of increasing the coordination number [48]. For example, the reactivity of tetravalent alkoxides in hydrolysis reactions decreases in the order $Si(OiPr)_4 \ll Sn(OiPr)_4$, $Ti(OiPr)_4 < Zr(OiPr)_4 < Ce(OiPr)_4$. The reactivity of some metal alkoxides is so high that precipitates are spontaneously formed upon addition of water. Whereas the reactivity of alkoxysilanes has to be promoted by catalysts, the reaction rates of metal alkoxides must be moderated to obtain gels instead of precipitates. The most common method is the addition of acetic acid or acetylacetone to the precursor solution. This results in partial substitution of the alkoxy groups by acetate or acetylacetonate. Other bidentate anionic ligands (L) can also be used [49]. The complexes $[\{M(OR)_y(L)_x\}_n]$ have a different reactivity, structure, and functionality compared to the unsubstituted alkoxide $M(OR)_{y+x}$ depending on the type and number of ligands. Complexation allows the chemical design of the precursors, so that the properties of the sol – gel materials can be deliberately influenced.

Compared to aerogels with a silicate network, only little work has been done to elucidate the network formation and structure of metal oxide gels. One of the most important differences is the possibility of forming crystalline primary particles. Generally, crystallinity is favored by a large excess of water in the hydrolysis reaction.

Alumina. The preferred precursors for the synthesis of Al_2O_3 aerogels are $Al(OsecBu)_3$ (ASB) and $Al(OtBu)_3$ (ATB) [50-54]. ASB has the advantage of being soluble in 2-butanol, while other aluminum alkoxides are insoluble in the corresponding alcohol. There are different possibilities for handling this problem [55]. The alkoxide can be dissolved in benzene followed by addition of pure water (two liquid phases are formed), or water dissolved in the corresponding alcohol. Alternatively, a dispersion of the alkoxide in the corresponding alcohol can be prepared and then water is added.

Titania and Zirconia. For the preparation of TiO_2 and ZrO_2 aerogels, the propoxides and butoxides of the metals are mainly used as precursors [50], [56-60]. As for the alumina gels, the amount of water added for hydrolysis is decisive for the structure of zirconia aerogel networks. Substoichiometric addition of water results in an amorphous network, while with an excess of water the structure is composed of crystalline, monoclinic ZrO_2 particles [3], [50]. When $Zr(OnPr)_4$ was gelled in 1-propanol in the presence of acetic acid, the acetate ligand remained in the aerogel [61].

TiO_2 aerogels can be prepared totally amorphous or with a network of anatase primary particles [62-64]. It was shown by a combination of SAXS, small-angle neutron scattering (SANS), BET measurements, and electron microscopy that mesoparticles of about 50 nm in diameter are formed by aggregation of the crystalline nanoparticles of about 5 nm diameter. The mesoparticles aggregate to give a three-dimensional network. A branched, polymerlike fractal structure was concluded from SAXS data on amorphous and partially crystalline ZrO_2 aerogels consisting of small primary particles with an average diameter of 5.2 nm (partially crystalline) or 2.5 nm (amorphous) [65], [66].

Other single-component oxide aerogels are listed in Table 3.

Table 3. Other inorganic aerogels, precursors for their preparation, and potential applications

Aerogel	Precursor*	Application
V_2O_5	$[VO(OiPr)_3]$ [67], [68]	cathode in lithium batteries
	$[VO(OEt)_3]$ [69-71]	
Cr_2O_3	$[Cr(NO_3)_3]$ [72]	oxidizing properties, fluorination of hydrocarbons with HF
	$CrCl_3$ [73]	
	$Cr(OAc)_3$ [74], [75]	
Fe_2O_3	$FeCl_3$ [72], [73]	
	$[Fe(acac)_3]$ [76-78]	
MoO_2	$[MoO_2(acac)_2]$ [50], [79], [80]	electrocatalysis
Nb_2O_5	$Nb(OEt)_5$ [81-83]	isomerizations, solid acid
MnO_2	$NaMnO_4 \cdot x\ H_2O$ [68], [84]	charge-storage applications
NiO	$NiCl_2 \cdot 6\ H_2O$ [85]	semiconductor, catalytic properties
CdS	$Cd(NO_3)_2 \cdot x\ H_2O$ [86]	photovoltaic and sensing applications

* acac = acetylacetonate.

A newer sol – gel route has opened access to a wide variety of transition and main group metal oxide aerogels such as Cr_2O_3, Fe_2O_3, Al_2O_3, In_2O_3, Ga_2O_3, SnO_2, HfO_2, ZrO_2, Nb_2O_5, Ta_2O_5, and WO_3 by use of epoxides as gelation agents [85], [87-89].

Binary and Ternary Oxide Aerogels. Compared to other methods for the preparation of multicomponent oxides, the sol – gel method offers the best control over the resulting materials properties. This is achieved by variation of the processing parameters [79], [90], [91].

When precursors with similar hydrolysis and condensation rates are mixed, mixed metal oxides are obtained which are homogeneous on a molecular scale. With larger differences in reaction rates, the microstructure of the product becomes more heterogeneous, and phase separation may even occur. In particular, the so-called core/shell phenomenon is observed. The faster reacting compound forms sol particles which are coated by the slower reacting component. There are several possibilities for avoiding this effect: The reaction rate of the faster reacting component can be moderated by using bidentate ligands. Alternatively, the slower reacting precursor can be prehydrolyzed and the faster reacting component added afterwards [92]. The network in the aerogels thus prepared is analogous to that of the one-component oxide aerogels.

Another option is the impregnation of a preformed silica alkogel with a metal alkoxide in a supercritical medium, as shown for titanium alkoxides [93].

Selected examples are listed in Table 4. Mixed oxide aerogels for catalytic applications are summarized in review articles [3], [5].

Table 4. Examples of binary and ternary oxide aerogels

Aerogel	Precursor*	Application
TiO_2 – SiO_2	[Ti(O*i*Pr)$_4$ + acac] + Si(OMe)$_4$ [94], [95]	epoxidation of olefins
Al_2O_3 – SiO_2 [96]	[$AlCl_3$ + ethylene oxide] + Si(OEt)$_4$ [73]	catalyst support
	Al(OAc)$_3$, Al(acac)$_3$	
3 Al_2O_3 – 2 SiO_2 (mullite)	(ASB + β-diketone) + Si(OEt)$_4$ [97]	preparation of high-purity ceramics
Fe_2O_3 – SiO_2 [98]	Fe(acac)$_3$ + Si(OMe)$_4$	Fischer – Tropsch syntheses
Fe_2O_3 – Al_2O_3	Fe(acac)$_3$ + ASB	
V_2O_5 – MgO	V(acac)$_3$ + Mg(OMe)$_2$ [99]	ammonia synthesis
PbO – Al_2O_3	Pb(OAc)$_2$ + ASB [100]	nitroxidation of hydrocarbons to nitriles
PbO – ZrO_2	Pb(OAc)$_2$ + Zr(O*i*Pr)$_4$ [101]	
BaO – Al_2O_3	Ba[Al(O*s*Bu)$_4$]$_2$ + ASB	car exhaust catalysis
	Ba(1,3-butanediolate) + ASB [102]	
x Li_2O – (1 – *x*) B_2O_3	B(OBu)$_3$ + LiOMe [103]	
$PbTiO_3$	Pb(OAc)$_2$ + Ti(O*i*Pr)$_4$ [104], [105]	piezoelectric lead zirconate titanate (PZT) aerogels
$BaTiO_3$, $SrTiO_3$	Ba or Sr and Ti(O*i*Pr)$_4$ [106]	
Mn-FeO_x	$FeCl_3 \cdot 6\ H_2O$ + $MnCl_2 \cdot 4\ H_2O$ [107], [108]	superparamagnetic material
NiO – Al_2O_3 – MgO	Ni(OAc)$_2$ + ASB + Mg(OMe)$_2$	nitroxidation
NiO – SiO_2 – MgO	Ni(OAc)$_2$ + Si(OR)$_4$ + Mg(OMe)$_2$ [109]	
2 MgO – 2 Al_2O_3 – 5 SiO_2 (cordierite-like)	Si(OEt)$_4$ + ASB + Mg(NO$_3$)$_2$ [61]	

* acac = acetylacetonate.

SAXS investigations of Al_2O_3 – SiO_2 (mullite) aerogels, prepared from the alkoxides in the presence of bidentate ligands again lead to the postulation of a RLCA-related network [97]. Si/O building blocks are partially incorporated into the alumina clusters and partially integrated onto the surface of these particles. The SiOH groups at the surface of the clusters serve as condensation sites between the particles.

X-ray diffraction (XRD) showed that SiO_2 aerogels are always amorphous, while TiO_2, Al_2O_3, and ZrO_2 can also be partially crystalline [50]. In mixed oxide aerogels, the SiO_2 and Al_2O_3 portions are always amorphous [77], [78], [109-111]. However, crystalline aluminates are observed (for example, $NiAl_2O_4$). Selected structural data of nonsilicate aerogels are listed in Table 5. They vary decisively with the preparation conditions.

Table 5. Typical structural data of some nonsilicate aerogels

Aerogel	Density, g/cm^3	Porosity, %	Pore radius, nm	BET surface area, m^2/g	Particle morphology, nm
TiO_2 [112]	0.3 – 1	78 – 90	1 – 25	316 – 690	
ZrO_2 [50], [61], [69-71], [83]	0.2 – 0.3	84 – 96	10	81 – 480	2.5 – 5.2
Al_2O_3 [50], [54], [113]	0.13 – 0.18		5	123 – 616	22 – 25, platelike
Al_2O_3 – SiO_2 [97], [114], [115]	0.06 – 0.21		12		1 – 5 *
V_2O_5 [69], [116]	0.04 – 0.1	96		140 – 400	< 10 nm, fibrous

$V_2O_5 – GeO_2$ [70]	0.08	96			
Cr_2O_3 [110]	0.15 – 0.54			516 – 785	
$PbO – TiO_2$ [104]	0.7	77	1 – 4	260	35 – 55

* Controllable by means of the amount of added β-diketone [115].

Metal in Metal Oxide Aerogels. A second metal component in a gel need not necessarily result in a binary oxide aerogel. The use of alcohols for supercritical drying can result in the conversion of easily reducible oxides into metals, because alcohols have reducing properties. Metal particles can also be generated by subsequent reduction of the aerogels with hydrogen at high temperature or by introducing hydrogen into the autoclave during supercritical drying [117].

Aerogels are particularly well suited as carriers for catalytically active metals because of their high porosity. Detailed discussions can be found in review articles on aerogels as catalysts [3], [5].

For the incorporation of metal components into the gel matrix, previously formed aerogels can be impregnated with solutions of the corresponding metal salts (two-step process) [118], [119]. Alternatively, metal salts can be added to the precursor solution, which results in the incorporation of the metal compounds in the gel during sol – gel processing [72], [120]. Table 6 gives some examples of metal-doped aerogels and their application in catalytic reactions.

Table 6. Examples of metal-doped aerogels

Aerogel	Precursor for the metal	Application
1. Impregnation		
$Cu – SiO_2$, $Cu – MgO$	$[Cu(NH_3)_4(OH)_2]$ in alcohol [118]	
$Cu – ZnO – Al_2O_3$	$Cu(OAc)_2$ [121]	hydrogenation
$Pt – MoO_2$	$H_2[PtCl_6]$ in MeOH [119]	hydrogenation
$Pd – Al_2O_3$	$PdCl_2$ [122], [123]	car exhaust catalysis
$Pd – CeO_2$,		
$Pd – BaO – Al_2O_3$		
2. Sol – Gel method		
$Pt – TiO_2$	$PtCl_4$, $[Pt(acac)_2]$, $(NH_4)_2[PtCl_6]$ [124]	hydrogenation
$Pd – Al_2O_3$	$[Pd(OAc)_2]$ [125]	car exhaust catalysis
$V – SiO_2$	$V(OiPr)_3$	
$Cu – SiO_2$	$Cu(OAc)_2$ [126]	
$Pt – Al_2O_3$	$H_2[PtCl_6]$ [127]	dehydrocyclisation

2.1.2. *Inorganic/Organic Hybrid Aerogels*

The goal of modifying oxide aerogels with organic groups is to supplement new properties without influencing the existing positive properties, such as good thermal insulation, transparency, and high surface area. For example, the hydrophobicity and elastic properties of SiO_2 aerogels can be improved relative to unmodified SiO_2 aerogels by incorporation of organic groups [128-130], or new applications can be envisioned by the integration of functional organic groups, for example, in catalysts or sensors.

There are only limited possibilities for post-synthesis doping or modification of aerogels with organic compounds (Section Modification of Aerogels after Drying). A more general route is the integration of organic entities in sol – gel processing.

Embedding molecules in gels without chemical bonding (Fig. 6 b) is achieved by dissolving these molecules in the precursor solution. The gel matrix is formed around them and traps them. The doped wet gels can, in principle, be converted to aerogels. However, the probability is very high that the organic groups are leached during the generally applied supercritical drying and the rinsing processes connected with it. For example, a fluorescent dye was incorporated in the gel network, but the portion retained during aging and drying was relatively low [131]. C_{60}/C_{70} was also incorporated into SiO_2 aerogels by this method [132]. Larger entities such as biomolecules (e.g., lipase) and microorganisms (e.g., *E. coli*) can be immobilized on silica aerogels and have great potential as biosensors [133], [134].

Aerogels with interpenetrating, but not interconnected, inorganic and organic networks (Fig. 6 a) were produced by generating the organic polymer in situ during the sol – gel reaction by radical polymerization of a vinyl monomer followed by supercritical drying with CO_2 of the dual-network gel. Attempts to perform the sol – gel process in solutions of organic polymers mostly failed, because the polymer was leached during supercritical drying. There was only success with organic

polymers capable of forming hydrogen bonds to the surface silanol groups of the inorganic matrix, such as poly-2-vinylpyridine (PVP) [135].

Figure 6. Inorganic/organic hybrid networks from sol – gel processing a) Interpenetrating inorganic and organic networks; b) Incorporation of organic molecules (enzymes, dyes, etc.); c) Organic modification (functionalization) of oxidic materials; d) Dual networks

The more important organic modifications of oxide aerogels are based on covalent bonding of the organic groups (Figure 6 c, d). In silicate systems, compounds of the type $R'Si(OR)_3$ are usually employed, where R′ is the organic group that modifies the inorganic gel. In nonsilicate systems, the organic groups can be introduced by means of bidentate ligands (Section Metal Oxide Aerogels). The preparation of organically modified xerogels is described in review articles [48], [49], [136].

Silica aerogels modified by nonfunctional or functional organic groups are prepared by sol – gel processing of $R'Si(OR)_3/Si(OR)_4$ mixtures (Eq. 3) followed by supercritical drying of the wet gels.

$$xR'Si(OR)_3 + (1-x)Si(OR)_4 + H_2O/ROH \rightarrow R'_xSiO_{(2-0.5x)} \cdot H_2O/ROH$$

When the organic groups R′ have no or only weakly basic properties, such as unsubstituted alkyl or aryl groups, or chloro, thio, phosphino, carbamato, glycidoxy or methacryloxyalkyl groups, sol – gel processing of the $R'Si(OR)_3/Si(OR)_4$ mixtures under base-catalyzed conditions is a two-step process, similar to the formation of core/shell multicomponent oxide aerogels (Section Metal Oxide Aerogels). The basic gel network is almost exclusively built by hydrolysis and condensation of $Si(OR)_4$, because reaction of $Si(OR)_4$ is faster than that of $R'Si(OR)_3$. Only in the second stage of the process are the $R'SiO_{3/2}$ units condensed onto the inner surface of the existing silica gel network. Inorganic/organic hybrid aerogels prepared from $R'Si(OR)_3/Si(OMe)_4$ mixtures therefore have the same structural features as those prepared from $Si(OR)_4$ alone, and the typical aerogel properties are retained. As long as the group R′ has no basic properties, the nature of R′ has no major influence on network formation and network structure, and only the fractal dimension of the primary particles is influenced by the polarity of the functional group [137-141]. Increasing the $R'Si(OR)_3$ fraction leads to larger primary particles and therefore lower specific surface areas. These structural phenomena result from the larger amount of water and catalyst that act on $Si(OR)_4$ in the first stage of the reaction due to the delayed reaction of $R'Si(OR)_3$.

When R′ in the $R'Si(OR)_3/Si(OR)_4$ mixture has basic properties, as in $(RO)_3Si(CH_2)_3NR'_2$ ($NR'_2 = NH_2$ or $NHCH_2CH_2NH_2$), both silanes are involved in the build-up of the gel network, and the two-stage process is no longer observed. The basic groups catalyze the sol – gel reactions [142], [143].

In another approach, the morphology (pore size, surface area) of the aerogels is tailored by linking $Si(OR)_3$ groups with an organic spacer. Compounds of the type $(RO)_3Si–X–Si(OR)_3$ with variable length and composition of the spacer X (e.g., saturated or unsaturated hydrocarbon chains, polyaryls) have been used. An inorganic oxidic network is formed during sol – gel processing in which the organic spacers X bridge the inorganic building blocks. When precursors of the type $(RO)_3Si(CH_2)_nSi(OR)_3$ (n = 2, 6, 8, 10, 14) were processed without the addition of $Si(OR)_4$ both under basic and acidic conditions, the length of the spacer n had a decisive influence on the resulting aerogel structure [144]. Ethylene- and hexamethylene-modified gels were highly porous and had high specific surface areas (about 700 m^2/g). The specific surface area decreased with increasing length of the spacer.

2.1.3. *Organic Aerogels*

Purely organic aerogels were synthesized by polymerization of multifunctional organic monomers in dilute solution, followed by supercritical drying [145-151]. Gelation of resorcinol/formaldehyde (RF) and melamine/formaldehyde (MF) mixtures was initiated by Na_2CO_3 or NaOH. The gels were then treated with dilute acid to increase the degree of cross-linking and thus stabilize the network. The most important parameter is the catalyst concentration or the pH of the solution. The structure and properties of the organic gels, such as density, specific surface area, and particle and pore sizes, can be deliberately influenced by these variables.

Resorcinol is a trifunctional monomer which can add up to three equivalents of formaldehyde. These substituted resorcinol derivatives then condense by formation of nanosized clusters, which then cross-link via the surface groups (for example, $–CH_2OH$). For the polymerization of melamine with formaldehyde, either the monomers or melamine – formaldehyde polymers of low molecular mass can be used [152].

Newer developments in the area of organic aerogels are based on the polymerization of furfural with a phenolic Novolak resin (prepared by reaction of phenol with formaldehyde) to give the so-called PF gels and polymerization based on polyaddition reactions of polyols and polyisocyanates to give polyurethane gels. A decisive advantage compared with RF or MF polymerization is that alcoholic solutions can be used. The laborious solvent exchange before drying is thus avoided

[153], [154].

Despite the structural differences originating from the different precursors, organic aerogels have some common properties, such as small, accessible pores (≤ 50 nm), high specific surface areas (400 – 1000 m^2/g), and a solid matrix which is composed of interconnected colloidal particles or polymeric chains of about 10 nm in diameter. Table 7 lists some representative data for organic aerogels.

Table 7. Some typical structural data and properties of organic aerogels

	Resorcinol – formaldehyde (RF)	Melamine – formaldehyde (MF)	Phenol – furfural (PF) [153]
Density, g/cm^3	0.03 – 0.6	0.10 – 0.80	0.10 – 0.25
Surface area, m^2/g	350 – 900	875 – 1025	385
Pore diameter, nm	50	50	
Particle morphology, nm	3 – 20	2 – 10	irregular shape, ca. 10 nm size,
Use	precursor for carbon aerogels		precursor for carbon aerogels
Color	dark red, transparent	colorless, transparent	dark brown

RF and MF aerogels consist of interlinked colloidal particles formed during sol – gel processing. The size and the number of the clusters strongly depends on the resorcinol/catalyst (R/C) ratio. Typical R/C values are in the range of 50 – 300. High catalyst concentrations (e.g., R/C = 50) result in particles with diameters of 3 – 5 nm, interconnected by broad particle necks (polymeric gels). If the R/C value is increased to 200 – 300, the particle diameter increases (11 – 14 nm) and they cross-link like pearls on a string (colloidal gels) [152]. No fractal character was found for organic RF aerogels in SAXS experiments [155]. Nanophase separation, both initiated and limited by cross-linking, was discussed as an alternative explanation for network formation [156].

2.2. Drying Methods

The evaporation of the liquid from a wet gel proceeds in a very complex way. In the first stage, the gel shrinks by the volume that was previously occupied by the liquid. The liquid flows from the interior of the gel body to its surface. If the network is compliant, as in alkoxide-derived gels, the gel deforms (Figure 7).

Figure 7. Representation of the contracting surface forces in pores of different size during drying. At the same pressure, the curvature of all menisci in the pores is the same. For this reason the larger pores are emptied first (after [32])

On shrinkage, OH groups on the inner surface approach each other and can irreversibly form M–O–M bridges. As drying proceeds, the network becomes increasingly stiffer, and the surface tension in the liquid rises correspondingly because the pore radii become smaller. The second stage of the drying process begins when the surface tension is no longer capable of deforming the network and the gel body becomes too stiff for further shrinkage. This point is called the critical point. (The critical point of the drying process should not be mistaken for the critical point at which a liquid changes into the supercritical state.) At this stage the tension in the gel becomes so large that the probability of cracking is highest. Although the liquid/gas interface retreats into the gel body, a contiguous funicular liquid film remains on the pore walls, that is, most of the liquid still evaporates from the exterior surface of the gel body. In the third stage of drying, this film is ruptured. Eventually, there is only liquid in isolated pockets, which can leave the network only by diffusion via the gas phase [17], [157].

Two processes are important for the collapse of the network: First, the slower shrinkage of the network in the interior of the gel body results in a pressure gradient which causes cracks. Second, larger pores are emptied faster than smaller pores during drying, so that if pores of different radii are present, the meniscus of the liquid drops faster in larger pores (Fig. 7). The walls between pores of different size are therefore subjected to nonuniform stress and therefore crack.

The parameters influencing these capillary forces are well investigated, and strategies were developed to avoid cracking. Important options are, inter alia, the pore size (larger pores are advantageous, because the capillary force is inversely proportional to the pore radius) [158], [159], aging (the network becomes stiffer), and addition of tensides (reduction of the surface energy leads to a decrease in capillary forces), organic templates, or drying control chemical additives (DCCA) [160-164]. Crack-free xerogels can be obtained by exact control of these parameters, although large shrinkage cannot be avoided.

This is not sufficient for the production of aerogels. Methods must be applied which both conserve the pore structure of the wet gels and avoid shrinkage.

2.2.1. *Supercritical Drying*

In supercritical drying, the solvent is put into the supercritical state, so that the liquid/gas interface in the pores disappears.

The wet gel is placed in an autoclave and covered with additional solvent. Drying of the samples, which would lead to the formation of cracks, is thus avoided. After closing the autoclave, the temperature is slowly raised, resulting in a pressure increase (path A in Fig. 8). Both the temperature and the pressure are adjusted to values above the critical point of the solvent (p_c, T_c) and kept at these values for a certain period. This ensures that the autoclave is completely filled with the supercritical fluid. The fluid is then slowly vented at constant temperature, while the pressure drops. When ambient pressure is reached, the vessel is cooled to room temperature and then opened. Drying is often performed with the vessel pre-pressurized by nitrogen to avoid evaporation of the solvent (path B in Fig. 8) [165]. The phase boundary between the liquid and the gas need not be crossed during drying.

Figure 8. Schematic representation of the principle of supercritical drying. At the critical point [T_c, p_c] the density of the liquid and the gas are equal. Supercritical drying can be performed along path A or B

2.2.1.1. *Drying in Organic Solvents*

The pore liquid, which is usually an alcohol or acetone due to the preparation conditions, is used as the supercritical fluid. About 250 °C and 7 MPa are needed to put these solvents in the supercritical state. Problems arise from the combination of high temperature, high pressure, and the flammability of the solvents [166].

Furthermore, rearrangement reactions in the gel network are highly probable because of the high temperature. For example, when aerogels are dried with alcohols, a modification of the surface may occur by conversion of M–OH to M–OR groups, or processes such as those occurring during aging and ripening of the gels are accelerated. Small pores are thus filled, and particle necks are strengthened. As a consequence, the resulting aerogels have a lower specific surface area, a narrow pore radius distribution (elimination of microporosity), and a stiffer network [167-170]. Organic groups may be destroyed during drying [171]. Phase separation and loss of stoichiometry (SiO_2 – B_2O_3, SiO_2 – Bi_2O_5 [172]) or crystallization (SiO_2 – TiO_2 [173]) may occur in multicomponent gels [5], [174].

2.2.1.2. *Supercritical Drying with CO_2*

An alternative to drying in organic solvents is the use of liquid carbon dioxide [175-177]. This method has the advantage of a very low critical temperature at a moderate critical pressure. However, time-consuming solvent exchange is necessary before drying. Another requirement is the miscibility of the pore liquid with carbon dioxide. For example, water and CO_2 are immiscible; therefore, an intermediate solvent exchange (e.g., water against acetone) is necessary [103]. Structural changes, as observed during supercritical drying with alcohols, only take place to a minor extent with CO_2. Therefore, the network of the wet gel can be conserved almost unchanged.

A modification of this method and its application in a continuous plant in which CO_2 is recycled is described in [178]. Heating and cooling of the autoclave is avoided by exchanging the solvent with supercritical CO_2.

Deliberate structural changes were induced in SiO_2/TiO_2, ZrO_2, and Nb_2O_5 aerogels by variation of the temperature above T_c during supercritical drying with CO_2. For example, the ratio between crystalline and amorphous fractions can thus be influenced, which is important for catalytic applications [179].

2.2.2. ***Freeze Drying***

Another possibility to avoid phase boundaries between the liquid and the gas phase during drying is freeze drying. The pore liquid is frozen and then sublimed in vacuo. There were some attempts to use this method for the production of aerogels [180-182]. However, the aging period must be extended to stabilize the gel network, the solvent must be replaced by one with a low expansion coefficient and a high sublimation pressure, and low freezing temperatures are attained by addition of salts. Another disadvantage is that the network may be destroyed by crystallization of the solvent in the pores. Cryogels are therefore only obtained as powders.

2.2.3. ***Ambient Pressure Drying***

Supercritical drying is the most expensive and riskiest part of the preparation of aerogels and must be dispensed with if aerogels are to become of interest for large-scale commercial applications. Therefore, the interest in other possibilities for exchanging the pore liquid in the gels by air is very high.

The capillary forces exerted by the meniscus of the pore liquid and the pressure gradient due to the shrinkage of the network are the main reasons for the collapse of the filigree structure. Drying of the gels under ambient conditions (also known as subcritical drying) requires strengthening of the network to avoid its collapse (irreversible shrinkage). Additionally or alternatively, the contact angle between the pore liquid and the pore walls must be influenced by deliberate modification of the inner surface and variation of the solvent to minimize capillary forces.

Ambient-pressure drying involves a series of solvent-exchange processes and modification of the inner surface [183], [184]. The water/alcohol mixture in the pores of the gel is first replaced by a water-free solvent, and the Si-OH groups at the surface are silylated, for example, with trimethylchlorosilane. The reactivity of the gel surface is thus reduced, and it is also hydrophobized. The actual drying process is performed after another solvent exchange. The gel shrinks strongly

during evaporation of the solvent from the pores, as expected. However, no irreversible narrowing of the pores by formation of Si–O–Si bonds is possible because of the silylation. Therefore, the gel expands to nearly its original size after reaching the critical point (spring-back effect). One of the prerequisites for this procedure is the strengthening of the network by exact control of the aging conditions. The network of the modified gels must be stable enough to tolerate a reversible shrinkage of up to 28 % of its original volume [185].

Similar good results were obtained by another strategy [186], [187]. The strength and stiffness of the network was drastically increased by aging the wet gels in solutions of tetraalkoxysilanes in aqueous alcohols. Shrinkage during drying was thus completely avoided. The monomers added during aging mainly condense in the smallest pores and at the particle necks. The microporosity of the gels is thus lost. The gels can also be dried at ambient pressure and 20 – 180 °C because of the stiffer network.

With the ambient-pressure drying technique for the preparation of aerogels, a technically much simpler and therefore less expensive method of preparation is available, which makes the industrial application of aerogels economically interesting [188]. A similar procedure based on solvent-exchange processes and drying under ambient conditions was successfully invented for the drying process of organic RF aerogels [189], [190].

Aerogels can be prepared as monoliths, granulates, or powders. However, many applications require porous films (coatings), for which supercritical drying is not a trivial issue. Nevertheless, aerogel films were synthesized in some laboratories [191], [192]. The possibilities provided by ambient-pressure drying eliminate the principal obstacles for preparing highly porous films [193].

2.3. Modification of Aerogels after Drying

Chemical modifications are still possible after drying. However, post-synthesis treatment with a liquid phase is problematic because wet gels are formed again.

Aerogels can be doped with metals by impregnation with a metal salt. The metal salt has to be introduced in alcoholic solution, and then the solvent has to be removed again in another supercritical drying step to prevent destruction of the aerogel network [121]. Another, more general possibility for the subsequent modification of aerogels is their reaction with gaseous compounds. For example, gaseous dichlorodimethylsilane or other silylating agents were employed to hydrophobize the aerogel permanently [194]. Deposition of carbon by decomposition of gases such as acetylene, methane, propane, xylene, or furfuryl alcohol was used to improve the thermal properties of aerogels [195-202], [203].

The chemical vapor infiltration (CVI) method was employed to prepare SiO_2 – Si nanocomposites by reaction with SiH_4 or $HSiCl_3$ and for the deposition of iron particles from ferrocene [204]. Reaction of SiO_2 aerogels with $[W(CO)_6]$ and subsequent thermal decomposition of the metal carbonyl in the aerogel resulted in metallic tungsten particles. WN or WS_2 particles in aerogels were formed by aftertreatment of the metal-doped aerogels with ammonia or sulfur. SiO_2 aerogels were analogously treated with gaseous $[Fe(CO)_5]$. In an oxidizing atmosphere, amorphous iron oxide/SiO_2 aerogels were obtained, which in subsequent reactions were transformed into Fe_3O_4/SiO_2 (by reaction with additional $[Fe(CO)_5]$) or to Fe_9S_{10}/SiO_2 aerogels (by reaction with H_2S), for example [205].

Organic compounds can also be sublimed into the network via the gas phase, as shown for a porphyrin derivative [206].

Beside the treatment of aerogels with gaseous compounds, pyrolysis of organic groups which are part of the aerogel structure is another possibility for modifying aerogels. The coating of the inner aerogel surface with carbon structures was thus achieved [203].

Carbon aerogels are of particular interest because they are electrically conducting [207-210]. They can be made by pyrolysis of resorcinol/formaldehyde or phenol/furfural aerogels under an inert atmosphere (1050 °C, N_2). Their structure and morphology basically corresponds to that of the precursor gels, that is, they are colloidal or polymeric (Table 8). The colloidal gels have spherical particles with diameters of 12 – 15 nm which are loosely connected by graphitic ribbons. The polymeric gels have smaller particles (7 – 9 nm) connected by broad particle necks. The precursor to catalyst ratio during the preparation of the organic gels and the pyrolysis temperature have the largest influence on the properties of carbon aerogels.

Table 8. Typical structural data of carbon aerogels

Skeletal density, g/cm^3	2.06
Density, g/cm^3	0.05 – 0.80
Specific surface area, m^2/g	600 – 800
Pore size, nm	< 50
Particle morphology, nm	3 – 20, amorphous
Appearance	black, opaque

[Top of Page]

3. Properties

3.1. Structural Properties

The microstructure of aerogels strongly depends on the preparation conditions and the choice of precursors. Therefore, each aerogel has its own structural characteristics (Chap. Synthesis).

The gathering of information on the structure of aerogels requires methods which cover the length scale from the lower nanometer range (structure of the primary particles) to the micrometer range (linking of the particles, etc.) [211]. No single method can provide the complete information. Some common methods for the structure determination of aerogels are mentioned in Table 9.

Table 9. Typical methods for the structural characterization of aerogels and the structural information available therefrom

Method	Structural information	Remarks/problems
N_2 adsorption and desorption (BET) [212]	specific surface area	only pores which are accessible to N_2 are detected
	pore radius distributions [213]	structural changes caused by the N_2 pressure during the measurements results in falsification of the values for the pore radii [214]
	adsorbent/ adsorbate interactions	
Helium pyknometry [215]	skeletal density	
Mercury porosimetry [216]	pore volume	compression of the network by the applied pressure instead of penetration of Hg into the matrix [217], [218]
Electron microscopy SEM (scanning), TEM (transmission), STEM (scanning transmission electron microscopy)	particle size	sintering processes due to the high energy of the electron beam
	form and arrangement of the particles (morphology)	
Light scattering		
Small angle X-ray scattering (SAXS)	particle and cluster sizes	inverse relation of the scattering vector and the structural dimension
	fractal dimensions	
Small angle neutron scattering (SANS)	surface area	information from the Ångstrom to the micrometer range
Nuclear magnetic resonance (NMR)	structure evolution from the molecular precursors to the gel stage [219], [220]	
	pore diameters or fractal dimensions [221], [222]	
Atomic force microscopy (AFM)	atomic structure at the surface [223]	

3.2. Physical and Chemical Properties

3.2.1. *Optical Properties*

The optical properties of SiO_2 aerogels and derived inorganic/organic hybrid aerogels vary between transparent and translucent, depending on the preparation conditions. This means that the structure-forming units are smaller than the wavelength of visible light. However, inhomogeneities in the network in the nanometer range result in Rayleigh scattering. Therefore, aerogels appear yellowish under light and bluish against a dark background. The portion of Rayleigh scattering correlates directly with the homogeneity of the gel network in the nanometer range. Objects that are viewed through an aerogel tile appear slightly blurred. Inhomogeneities in the micrometer range at the exterior surface of the aerogel body are responsible for this phenomenon [224].

For most applications a high optical transmission is desirable; therefore, numerous attempts were made to influence the optical properties. Improvements were achieved by physical approaches such as desorption of water, different drying procedures, and adjusting the synthesis conditions [4], [177], [225-232].

3.2.2. *Mechanical and Acoustic Properties*

Mechanical properties have many aspects. Among others, rigidity, brittleness, and dimensional stability, as well as the method of investigation, have to be considered. Although the rigidity of aerogels is low because of their structure and the brittleness of the SiO_2 particles, it is sufficient for most applications. The compressive strength of monolithic SiO_2 aerogels is in the range 0.15 – 0.30 N/mm^2, depending on the density, with an elastic compression of about 2 – 4 %. The rigidity in vacuum is distinctly higher. The tensile strength is about 0.020 N/mm^2 [233].

One of the decisive parameters for the mechanical properties is the interconnection of the network in the nanometer range, which strongly depends on the preparation conditions. For example, aerogels prepared under acidic or neutral conditions are about twice as stiff as the corresponding samples prepared under base-catalyzed conditions [234]. Investigations of organically modified aerogels showed that the elastic properties of SiO_2 aerogels can also be improved by using chemically modified precursors. Since the longitudinal sound velocity is related to one of the elastic constants (which correlates with Young's modulus) and the density of the aerogel, ultrasound measurements were used for these investigations. The reason for the improved elastic properties of hybrid aerogels is probably that the presence of alkyl or aryl groups on the surface of the secondary particles impairs stiffening of the particle necks by Ostwald ripening [141], [235].

The particular network structure of aerogels results in impressive acoustic properties which, as mentioned above, correlate with the elastic properties [236]. The sound velocities in SiO_2 aerogels of 100 – 300 m/s are among the lowest for inorganic solids (which is noteworthy when one considers that sound velocities of 5000 m/s were measured in quartz glass) [237], [238]. SiO_2 aerogels have the lowest acoustic impedance of all solid materials ($Z = 10^4 – 10^5$ kg m^{-2} s^{-1}).

3.2.3. *Thermal Conductivity*

The thermal conductivity of aerogels is made up of three contributions: thermal transport by the gas phase, by the solid phase, and by radiation. Figure 9 schematically shows the contribution of these components as a function of bulk density.

Figure 9. Composition of the thermal conductivity of aerogels: gas, solid and radiation transport as a function of the density of the material (reprinted from [239] with permission of Spektrum der Wissenschaft Verlag)

The solid conductivity clearly increases with increasing density, whereas the reverse is true for the gas and radiative transport. The minimum for the total thermal conductivity is at a density of about 0.150 g/cm^3 [239]. Heat transport by the gas phase can be avoided by evacuation of the system. For example, an evacuated SiO_2 aerogel at about 300 K shows a thermal conductivity of only 0.010 W m^{-1} K^{-1}, compared to 0.020 W m^{-1} K^{-1} in air [240]. This is not a specific property of SiO_2 aerogels. Thermal conductivities as low as 0.012 W m^{-1} K^{-1} were measured for nonevacuated organic RF aerogels [241].

Another possibility for lowering the thermal conductivity of SiO_2 aerogels is to reduce the radiative heat transport. This is more important for high-temperature applications, because the radiation maximum is then in a wavelength range in which SiO_2 does not sufficiently absorb (3 – 5 µm). Reduction of thermal conductivity at these temperatures is possible by doping the aerogels with infrared opacifiers, such as carbon black or TiO_2. These compounds can be mixed in a highly disperse form with the precursor solution during sol – gel processing or with the sol [241]. Another possibility is the generation of carbon in the aerogel by pyrolysis of organic gases or covalently bonded organic groups of hybrid aerogels (see Sections Inorganic/Organic Hybrid Aerogels and Modification of Aerogels after Drying). The latter method leads to a particularly efficient decrease of the thermal conductivity (0.012 W m^{-1} K^{-1} in air at 300 K), because the aerogel skeleton is partially covered with nanosized carbon structures [242].

3.2.4. *Hydrophobicity*

A major drawback of unmodified SiO_2 aerogels, in particular for technical use, is their long-term instability under a humid atmosphere. Owing to the large number of silanol groups on the inner surface of the material, adsorption and capillary condensation of water and eventually cracking of the gel body by the resulting capillary forces results. Approaches to permanently hydrophobize aerogels were therefore investigated early on. The possibility of treating an aerogel subsequently with a silylating agent has the disadvantage of complicated processing. This kind of modification is only possible via the gas phase (see Section Modification of Aerogels after Drying).

Hydrophobation at the alcogel stage is time-consuming, since the diffusion rate of the silylating reagent into the pores is a limiting factor. However, this process is a key step in the prevailing ambient-pressure drying of aerogels (see Section Ambient Pressure Drying). Aerogels prepared by this method are inherently hydrophobic.

[Top of Page]

4. Applications

SiO_2 aerogels have the highest potential for applications. They are not only the best-investigated with regard to their preparation, structure, and properties, but can also be prepared with lower costs than other aerogels. There are already commercial applications. Nonsilicate aerogels (see Section Metal Oxide Aerogels) are playing an increasingly important role, particularly in the search for new catalysts. In the case of organic aerogels, mainly their pyrolysis products (carbon aerogels) offer interesting new applications [243].

4.1. Çerenkov Detectors

Çerenkov radiation is emitted by charged particles such as pions, muons, or protons when they exceed the speed of light in a medium. A cone-shaped electromagnetic shock wave is formed. The velocity of the particles can be calculated from the cone angle. The speed of light depends on the refractive index of the medium. SiO_2 aerogels with refractive indices between 1.007 and 1.024 offer a range not covered by the previously used compressed gases or liquids. As solid materials, aerogels additionally allow easier construction of the detectors and are therefore ideal materials for this application [239], [244]. They are now installed in several Çerenkov detectors worldwide, and the amount of aerogel tiles produced for this application is impressive. For example, at the Deutsches Elektronen-Synchroton (DESY) in Hamburg, a detector was supplied with about 1700 L of silica aerogel.

4.2. Thermal Insulation

Aerogels have the lowest thermal conductivities of all solids (Figure 10). They are among the best thermal insulation materials. Additional advantages are nonflammability and transparency.

Figure 10. Comparison of the thermal insulation properties of some commercially available insulating materials (PUR = polyurethane foam; CFC = chlorofluorocarbons; EPS, XPS = expanded and extruded polystyrene). (Reprinted from [188] with permission of Hoechst AG)

However, a major problem in the insulation of windows is the production of large aerogel panels [245]. Conventional windows cannot be equipped with the commonly prepared granulate, which is not transparent due to the roughness of its surface; it can only be used for frosted glass windows (for example, bathroom, staircase, or ceiling windows). The scattering of the sunlight in the granular layer is here rather advantageous, because diffuse lighting of the rooms is achieved.

In addition to transparent thermal insulation, applications for a variety of other insulation problems are conceivable for which transparency of the insulating material is not necessary, for example, in cooling or heating systems, high-temperature batteries, insulation for piping, heat and cold storage appliances, automotive exhaust pipes, transport vehicles and vessels, etc. Thin aerogel films can even be used for coatings on IR detectors to shield against the heat radiating from the substrate [7-11], [246-248].

Aerogels can also be utilized for passive exploitation of solar energy, for example for paneling of house walls (Figure 11) or for coating solar-energy collectors [249-253]. A layer of the transparent aerogel allows the penetration of the sun′s radiation to the blackened wall, but not the escape of the heat generated there [254].

Figure 11. Concept for energy saving by passive use of solar energy (reprinted from [239] with permission of Spektrum der Wissenschaft Verlag)

4.3. Catalysis

All the advantages of sol – gel processing for preparing catalysts or catalyst supports, especially the controllable dispersion of the active component and the possibility of deliberately influencing the microstructure, also apply for aerogels. Additionally, typical structural properties predestine them for these applications: the extremely high inner surface area (which is readily accessible because of the open porosity), the large pore volume, excellent temperature stability, and the high selectivities in catalytic processes. Most oxides relevant for catalytic applications can be prepared as aerogels, including binary and ternary compositions, mixtures of metal oxides, or metal particles on oxide supports. Furthermore, aerogels can be prepared as powders, granulates, or monoliths, either amorphous or with crystalline fractions.

Despite these obvious advantages, the use of aerogels in catalysis has only been increasingly investigated since 1974. Considerable progress was achieved in solving problems originating from the low density and the low thermal conductivity, that is, pressure drops and poor heat dissipation in the catalyst bed. For example, heat-dissipating materials can be added, or the aerogels can be deposited during their preparation (i.e., in the autoclave) on a support (such as Raschig rings, metal tubes, cordierite honeycombs, wire mesh screens, boiling stones, and others) [74].

It is impossible to list all the investigated systems here. They are summarized in specialist reviews [3], [5]. The following selection is intended to give an impression of the numerous possibilities: nitroxidation of hydrocarbons to nitriles (NiO – Al_2O_3 with SiO_2 and MgO, PbO – ZrO_2) [101], [111] hydrogenation of nitrobenzene to aniline and of toluene to methylcyclohexane (Ni – SiO_2, Pd – Al_2O_3) [125], hydrogenation and hydrogenolysis after hydrogen "spillover" activation (ZrO_2, SiO_2, MgO, Al_2O_3) [255], isomerizations (Nb_2O_5, Nb_2O_5 – SiO_2) [81], Fischer – Tropsch syntheses (Fe_2O_3 – Al_2O_3, Fe_2O_3 – SiO_2) [98], polymerization of ethene or propene ($TiCl_4$ – Al_2O_3) [256], deNO_x reactions (Fe_2O_3 – Cr_2O_3 – Al_2O_3, Pt – C) [151], [257], catalysis for combustion of car exhaust (Pd – Al_2O_3, Pt – Al_2O_3, Pd – Al_2O_3 – SiO_2) [123], [258], and fluorinations (Cr_2O_3) [75].

4.4. Application as Storage Media

The high porosity and very large surface area of silica aerogels can also be utilized for applications as gas filters, absorbing media for desiccation and (nuclear) waste containment, encapsulation media, and hydrogen fuel storage [2], [259-264].

Partially sintered aerogels can resist the tensions of a gas/liquid interface because their texture is strengthened during sintering. They can therefore be used for the storage, thickening, or transport of liquids, for example rocket fuels; in this case the low weight of aerogels is particularly advantageous [2]. Another potential application of aerogels relates to energetic materials. Traditional manufacturing involves processing of granular solids. Their performance strongly depends on the particle size distribution, surface area, homogeneity, etc. These issues could be improved by preparing detonators from aerogels [265].

4.5. Electrical and Electronic Applications

Carbon aerogels are very well suited as electrode materials for batteries and capacitors because of their low electric resistance (< 40 mΩ cm), controllable pore radius distribution (1 – 50 nm), and high specific surface area. When a voltage is applied, a thin polarization layer of high capacity is formed on the large surface. More charge can be stored than with conventional capacitors, because the surface area per unit volume of aerogels is very high. Compared to other materials (carbon powder or fibers), aerogels have the major advantage that they can be prepared as monoliths [207-210]. One of the most promising applications in this area is a cost-effective purification process using carbon aerogel electrodes for a variety of applications ranging from extracting harmful contaminants from industrial wastewater to desalinating sea water [266], [267].

Metal oxide and organic aerogels are excellent materials for low-dielectric applications. While bulk aerogels can be used for microwave electronics and high voltage insulators, thin aerogel films can compete with existing technologies in microelectronics. Here, the low dielectric constant of aerogels (< 2.0) plays a particularly important role. They offer important progress in the velocity of electric circuits. In addition, the dielectric constant is easily controlled because it is directly related to the porosity and hence the density of the materials.

Various metal oxide aerogels have been synthesized which exhibit superconducting, thermoelectric, or piezoelectric behavior [268-270].

4.6. Acoustic and Mechanical Applications

Aerogels have very low acoustic impedances and can therefore be used for matching the high acoustic impedance of piezo ceramics to the low impedance of air. The efficiency of these devices is considerably increased by decreasing the reflection losses at this interface [271], [272].

Aerogels have also been proposed as shock- and sound-absorbing materials (anechoic chambers) [272], [273]. Another interesting application is the use as sound-insulation material. The acoustic insulation performance of silica aerogel composite materials in the low frequency range is very good [274].

4.7. Optical Applications

Aerogels can be sintered at low temperatures and can therefore be processed into extremely pure and totally homogeneous glasses [275-280]. The inner surface area and the porosity decrease during sintering. The pore structure can therefore be modified in a controlled way by partial sintering. This was used, for example, for producing gas filters with pores in the range of 20 – 100 nm [281]. Doping of aerogels with dyes or rare earth elements allows the fabrication of glass for applications such as lasers and radioluminescent light sources [282-286].

Aerogel films can be exploited as optical coatings for solar cells because of their low refractive index (aerogel films prepared for this purpose are subsequently attached to the surface of the solar cell) [287]. The glass layers with high refractive indices otherwise used can thereby be replaced by aerogels. More light reaches the active surface because of the lower Fresnel scattering losses. These films have also been applied to the outside of fiber optics to improve the light collection and propagation efficiency.

4.8. Other Applications

There are numerous potential applications of aerogels. SiO_2 aerogels are suitable as ecologically acceptable insecticides against pests in grain and seeds, or those on the ground, such as mites, ticks, cockroaches, and silverfish [288-291]. As a chemically inert dust with small particles and a high specific surface area, aerogels can remove the protecting lipid layer of insects by abrasion or adsorption. They are then killed by rapid loss of body liquid.

Low-density silica aerogels can be used to study the superfluid transition of ^4He and phase separation of ^3He – ^4He mixtures [238].

SiO_2 aerogels are one of the standard media for collecting cosmic dust [292], and they are attached to the outside of spacecraft [293]. Aerogels have the advantage that they are extremely light with a unique mesostructure which is also transparent. This enables a soft landing of very fast extraterrestrial particles impinging with a velocity of more than 3 km/s, and also allows their subsequent investigation by optical methods.

[Top of Page]

5. Future Perspectives

The unique optical, thermal, acoustic, and mechanical properties of aerogels originate from the combination of a solid matrix (with a certain chemical composition) and nanosized pores filled with air. There is a direct connection between the chemistry of the sol – gel process and the structure of the gels, and between the structure and the properties of the aerogels. The choice of the precursors and the chemical reaction parameters already determines the physical properties of the final materials.

The possibilities originating from ambient-pressure drying will provide strong impetus to preparative chemical research, because aerogels can now be prepared with standard laboratory equipment. There is definitely room for more extensive chemical modifications of the property profile of aerogels.

The new drying techniques will probably make technical preparation much cheaper and will thus make aerogels more competitive. Apart from special applications in which material costs only play a minor role, the rather high price of supercritically dried aerogels mitigated against a broader range of applications. The most important area for the application of aerogels are all kinds of thermal insulation. There is no doubt about the physical and ecological advantages (nontoxic, nonflammable, easy to dispose of) of SiO_2 aerogels compared with most other materials on the market.

Abstract

The article contains sections titled:

1. Introduction
2. Fundamentals
2.1. Description of the Pore Liquid
2.2. Cake Formation
2.3. Washing of the Centrifuge Cake
2.4 Dewatering of the Centrifuge Cake
2.4.1. Equilibrium of Centrifugal Dewatering
2.4.2. Kinetics of Dewatering
3. Discontinuous Filtering Centrifuges
3.1. Cycles of the Discontinuous Centrifugation Process
3.2. Filling Strategies of the Centrifuge Drum
3.3. Peeler/Scraper Centrifuge
3.3.1. Horizontal Construction
3.3.2. Vertical Construction: Three Column Centrifuge
3.3.3. Siphon Centrifuge
3.4. Inverting Filter Centrifuge
3.5. Centrifugal Dryer
4. Filtering Centrifuges with Continuous Feed
4.1. Conical Screen Centrifuge
4.2. Vibrating Conical Screen Centrifuge
4.3. Tumbler Centrifuge
4.4. Screen Scroll Centrifuge
4.5. Pusher Centrifuge
4.5.1. Cake conveyance – Transport model
4.5.2. Washing on the Pusher Centrifuge
4.5.3. Feeding – Danger of Basket Flooding
4.5.4. Multistage Pusher Centrifuges
4.5.5. Special Pusher Centrifuges
4.6. Decanting Centrifuge/Solid Bowl Centrifuge
4.6.1. Application for Filtration Dewatering
4.6.2. Dewatering Model
4.7. Screen-Bowl Centrifuge
5. Hybrid Processes
5.1. Hyperbaric Centrifugation/Jet-Stream Centrifugation
5.2. Steam-Enhanced Centrifugation/Steam-Pressure Centrifugation
6. Laboratory-Scale Testing
6.1. Laboratory Centrifuges

7. Applications
8. References

1. Introduction

Centrifuges are machines which are primarily used in solid–liquid separation. The driving force is the centrifugal field, which acts differently on the particles and the mother liquid. Filtering centrifuges compete with filters (⟶ Filtration), press filters, and sedimenting centrifuges (⟶ Centrifuges, Sedimenting).

The field of application for filtering centrifuges is quite wide: minerals, fine chemicals, pharmaceutical products, food products, and bio suspensions. Therefore, different concepts for construction have been developed. Furthermore, most centrifuges are adapted in detail engineering to their application. Filtering centrifuges can be operated in continuous or discontinuous mode. The capacity can range from several kilograms up to more than 100 t per hour.

All filtering centrifuges have in common the dewatering process. First, a filter cake is formed on a permeable support, second, the liquid drains in the direction of the centrifugal field through the filter cake; third, desaturation begins, the liquid runs off the pores, and air penetrates the pores of the cake. The process comes to an end when the driving force of the centrifugal field is in equilibrium with the retaining forces in the pores, which primarily are due to wetting effects (Fig. 1).

Figure 1. Process phases during centrifugal filtration: sedimentation, drainage, and desaturation

a) Liquid surface; b) Clear liquid; c) Sedimenting suspension; d) Filtrate; e) Clear liquid; f) Centrifuge cake; g) Desaturated cake; h) Wet cake

The main component of a filtering centrifuge is the perforated drum or basket. Its interior is covered with a sieve or a filter medium. The rotation of the basket usually is powered by an electric drive. The performance of a centrifuge can be estimated by using the centrifugation number *C*, which is the ratio of the centrifugal acceleration to gravity. It depends on the angular velocity ω and the basket diameter *R*.

$$C = \frac{R\,\omega^2}{g} \tag{1}$$

Technical filtering centrifuges operate with a centrifugal number from about 100 up to 2000 or even higher (Fig. 2). The maximum rotary speed is limited by the mechanical stress and the durability of the steel used for construction.

Figure 2. Operational ranges for filtering centrifuges

a) Inverting filter; b) Peeler centrifuge; c) Screen scroll; d) Pusher centrifuge; e) Tumbler centrifuge; f) Pendulum centrifuge

The vertical lines perpendicular to the rotor-diameter axis and the rotational speed (*n*) lines from top right to bottom left intersect at the operating point. The ordinate of this intersection gives the centrifugal number *C*. Secondary parameter lines from top left to bottom right give the circumferential velocity *v*.

Table 1 gives an overview on the construction size and performance of the common types of filtering centrifuges. The solids throughput depends mainly on the suspension and particle properties, which must be estimated with laboratory-scale tests.

Table 1. Types of centrifuges: constructive and operation parameters

Centrifuge type	Rotor diameter, mm [1], [2]	Throughput, t/h [2], [3]	Maximum centrifugal number	Minimum particle size, µm [1], [3]	Minimum solids concentration, % [1], [3]
Peeler centrifuge	250–2000	0.1–15	1500 (2000)	5–10	10
Inverting filter centrifuge	400–1300		700–1100	2	5
Centrifugal dryer	400–1300		600–700	2	5
Conical screen centrifuge	500–800		1250–2400	50–80	15
Vibrating conical screen centrifuge		300	30–120	300	50

Tumbler centrifuge		200	50–300	200	50
Screen scroll centrifuge	200–1000	0.1–100	500–1500	80	20
Pusher Centrifuge	200–1560	2–100	300–1200	50	20
Decanting centrifuge			> 4000	70	4–5
Screen-bowl centrifuge	360–1000	0.2–30	1800–3200	20	4–5

[Top of Page]

2. Fundamentals

2.1. Description of the Pore Liquid

The pore liquid in a filter or centrifuge cake consists of differently bound liquid (Fig. 3). The main fraction is the liquid in the large interparticle pores (a), which are easily accessible. After drainage of the pore liquid, liquid bridges (b) remain within the porous system at the contact faces of the particles. They are bound by strong surface forces, as is liquid in the surface roughness of the particles (c). The inner porosity of the solid also contains liquid (d). Any particle surface is covered by a liquid surface film as well as with adsorbed liquid (e). Centrifugal dewatering is able to remove the liquid from the large pores. With large particle sizes some of the liquid bridges also can be removed by the centrifugal force. All other liquid cannot be removed by mechanical means in a centrifugal field or by filtration.

Figure 3. Pore liquid binding mechanisms in the porous matrix

a) Pore liquid; b) Liquid bridges; c) Liquid in surface roughness; d) Liquid in inner porosity; e) Adsorbed liquid film

The centrifuge cake is described by its geometry in the basket and its inner structure. The porosity ε is the ratio of void volume V_v in the cake to the entire cake volume V_c.

$$\varepsilon = \frac{V_v}{V_c} \tag{2}$$

Dewatering of the porous cake is quantified with different dimensionless numbers: the saturation S, which is the ratio of liquid volume to pore volume, the liquid load X, which is the ratio of liquid mass to solids mass, and the residual moisture R_M, which is the ratio of liquid mass to mass of wet cake.

$$S = \frac{V_L}{V_v} = \frac{V_L}{V_S \cdot \frac{\varepsilon}{1-\varepsilon}} \quad X = \frac{m_L}{m_S} \quad R_M = \frac{m_L}{m_L + m_S} \tag{3}$$

Due to its dependence on porosity, saturation is a more academic unit. Residual moisture and liquid load are derived from practical application.

2.2. Cake Formation

Cake formation in the drum must take account of the curvature of the filtering surface. The cake is built up as an annulus (Fig. 4). Thus, the area through which the liquid drains is a function of cake height. This must be considered when calculating the pressure drop.

Figure 4. Cake geometry

a) Filter medium; b) Cake; c) Clear liquid pool

The volume flux $\dot{V}$ can be written using the Darcy equation:

$$\dot{V} = -\frac{2\,\pi\, r L_{dr}}{\eta_L\, r_c} \cdot \frac{dp}{dr} \tag{4}$$

where r is the radius, L_{dr} the length of the drum, p the pressure, η_L the dynamic liquid viscosity, and r_c the specific cake

resistance.

Integration within the boundaries of drum radius R and radius of the cake surface r_S leads to the pressure drop as a function of the cake height (Eq. 5).

$$\Delta p = -\frac{\dot{V}\eta_L r_c}{\pi r L_{dr}} \cdot \ln\frac{R}{r_s} \tag{5}$$

This pressure drop of the volume flux is balanced by the driving centrifugal pressure of the liquid in the basket (Eq. 6). The liquid in the pores of the cake and the clear liquid in the pool above the cake surface r_L must be considered:

$$\Delta p = \frac{1}{2} \cdot \rho_L \omega^2 (R^2 - r_L{}^2) \tag{6}$$

where ρ_L is the liquid density.

The force balance when the pressure drop is equal to the driving centrifugal pressure allows the volume flux of filtrate draining off the cake to be determined (Eq. 7).

$$\dot{V} = \frac{\pi L_{dr} \rho_L \omega^2 (R^2 - r_L{}^2)}{\eta_L r_C \ln\frac{R}{r_S}} \tag{7}$$

In the case of small cake heights the equation can be simplified by replacing the logarithm (Eq. 7) by a linear term (Eq. 8).

$$\dot{V} = \frac{\pi L_{dr} \rho_L \omega^2 (R^2 - r_L{}^2)}{\eta_L r_C (R - r_S)} \tag{8}$$

The volume flux can be written with separated groups of parameters (Eq. 9): filtering surface, centrifugal acceleration, product parameter, and cake geometry.

$$\dot{V} = A_c C g \cdot \frac{\rho_L}{2 \eta_L r_C} \cdot \frac{(R^2 - r_L{}^2)}{R^2 \ln\frac{R}{r_S}} \tag{9}$$

The volume flux can be used to calculate the draining time in a centrifuge (Eq. 10). The drum usually is filled with a flow rate higher than the draining rate. Cake formation is an instantaneous process and the liquid remains above the cake. Subsequent to draining, a second filling step, a washing step, or desaturation occurs. With the focus on filling and washing it is necessary to predict the right moment when the liquid level reaches the cake surface:

$$\Delta t = \frac{\eta_L r_C \ln\frac{R}{r_S}}{\rho_L \omega^2} \cdot \ln\left(\frac{R^2 - r_{L,t=0}{}^2}{R^2 - r_S{}^2}\right) \tag{10}$$

The estimation of the filling time at the optimum feed flux, which is a function of the cake height in the basket, requires an extended mass balance [1].

2.3. Washing of the Centrifuge Cake

Cake washing is an essential process step to increase product quality. The mechanism and process design differ from continuous to discontinuous centrifuges. Continuous centrifuges are characterized by low specific washing liquid quantities from 20 to 200 kg/t_{solids}. Washing mainly is a film washing process. Film washing has its highest efficiency when the wash liquid is injected directly after cake formation, when the centrifuge cake has its highest saturation. The more liquid has drained from the pores, the more closed liquid compartments are created within the porous system. These are protected by the surface tension and therefore they are not directly accessible for the wash liquid. The wash liquid itself is sprayed onto the cake surface through pressure nozzles. The residence time of the cake in the centrifuge must be high enough to ensure that both the pore and the wash liquid are able to drain out of the cake. Usually the wash liquid prolongs the film flow phase of dewatering [4].

Discontinuous centrifuges use a washing mechanism which is similar to that used in filtration. The wash liquid flows in plug flow through the entirely saturated filter cake. The wash ratio, defined as was liquid per unit pore volume, in most cases is greater than one.

The washing step can be operated at lower rotation speed than dewatering. The liquid is softly laminated above the cake surface, which must be disturbed and resuspended as little as possible.

The wash liquid then drains through the cake. The flux can be calculated using the same equation as for the cake formation process (Eq. 7).

2.4. Dewatering of the Centrifuge Cake

The dewatering process can be split up into different subprocesses. Feeding of the suspension into the drum is directly coupled to cake formation. Cake formation by sedimentation is characteristic of centrifugal processes in which the solid density is higher than the liquid density. Formation of the cake is as instantaneous effect.

Subsequent to cake formation the liquid is forced by its own weight to drain through the porous sediment. Desaturation occurs when the surface forces can be overcome by the mass forces. Finally the dewatering process reaches an

equilibrium state.

2.4.1. *Equilibrium of Centrifugal Dewatering*

The driving force of the centrifugation process is the centrifugal pressure p_c (Eq. 11), which is calculated from the liquid density and the height of the liquid in the drum *H*:

$$p_c = \rho_L g C H \tag{11}$$

Using the approximation that the cake height is small compared to the drum diameter a simple force balance can be applied (Fig. 5). The filter cake is replaced by a capillary with a representative diameter. This diameter is called the hydraulic diameter (Eq. 12).

$$d_h = \sqrt{\frac{32\,\varepsilon}{r_c}} \tag{12}$$

where r_c is the specific filter cake resistance, and ε porosity.

Figure 5. Force balance in a characteristic capillary

a) Centrifugal force; b) Surface force; c) Pressure drop (shear force)

The driving force is the centrifugal force and the retaining force is the surface force:

$$\pi \cdot \frac{d_h}{4} \cdot \rho_L\, g C H - \pi\, d_h\, \sigma \cos \delta = 0 \tag{13}$$

Transformation of Equation (13) leads to the definition of the Bond number Bd_1 (Eq. 14):

$$Bd_1 = \frac{\rho_L\, g C d_h H}{\sigma \cos \delta} \tag{14}$$

The Bond number Bd_1 also can be seen as a reciprocal relative liquid height in the capillary. The Bond diagram (Fig. 6) shows the equilibrium of dewatering: Saturation is plotted versus Bd_1. Information on the minimal saturation for a given set of operation parameters can be drawn from the Bond diagram.

Figure 6. Equilibrium of dewatering, characteristic Bond-diagram

a) Saturation *S* = 1 — no dewatering; b) Bond plateau

The Bond diagram (Fig. 6) contains four characteristic areas:

- Bond I — no desaturation occurs, saturation is equal to one, and the surface force equals the centrifugal force.
- Bond II — desaturation begins, and with increasing *Bd* saturation decreases until all liquid is removed from the large interparticular pores.
- Bond III — the so-called Bond plateau; saturation remains constant, and to drain the liquid bridges the centrifugal force must be increased by at least one order of magnitude.
- Bond IV — this area is usually out of range for technical dewatering processes; the liquid bridges start to drain.

Filtering centrifuges are operated in Bond I to III, and continuous filtering centrifuges mainly in Bond III. Discontinuous filtering centrifuges operated in Bond II create a heterogeneous distribution of liquid within the cake. The cake near the filter cloth is saturated, and the cake near the surface is desaturated.

The description of the area Bond IV also uses a second Bond number (Eq. 15), which takes into account that the cake height is no longer an influencing parameter. The dimensionless number Bd_2 is calculated with the square of the hydraulic diameter, which is a characteristic length for the liquid bridges within the pores.

$$Bd_2 = \frac{\rho_L\, g C {d_h}^2}{\sigma \cos \delta} \tag{15}$$

The Bond diagram can also be plotted versus Bd_2, and different experimental results the form a master curve in the area Bond IV but spread in the area Bond II, where the cake height has its main influence on desaturation.

2.4.2. *Kinetics of Dewatering*

Estimation of dewatering kinetics is relevant to continuous centrifuges, which have a limited residence time from about 2 to 30 s. With the help of the capillary model (Fig. 5) the drainage of the liquid can be calculated taking into account the friction force of a laminar flow within the capillary. The force balance (Eq. 16) then includes friction, surface, and centrifugal forces:

$$-8\pi\ \eta\, x \cdot \frac{\mathrm{d}x}{\mathrm{d}t} - \pi\, d_\mathrm{h}\, \sigma\, \cos\delta + \pi \frac{{d_\mathrm{h}}^2}{4} \cdot \rho_\mathrm{L}\, g C x = 0 \tag{16}$$

The solution of the force balance leads to an implicit equation of the dewatering time and the time dependent position *x* of the liquid surface within the capillary (Eq. 17). The left side of the equation, which contains the time Δt, can be merged into the kinetic parameter. This kinetic parameter λ can be seen as a reciprocal time.

$$\frac{1}{8\lambda} = \frac{\Delta t \rho_\mathrm{L} g C d_\mathrm{h}^2}{32\eta H} = \left(1 - \frac{x}{H}\right) - \frac{4\sigma\cos\delta}{\rho_\mathrm{L} g C H d_\mathrm{h}^2} \cdot \ln\left[\frac{\frac{x}{H} - \frac{4\sigma\cos\delta}{\rho_\mathrm{L} g C H d_\mathrm{h}^2}}{1 - \frac{4\sigma\cos\delta}{\rho_\mathrm{L} g C H d_\mathrm{h}^2}}\right] \tag{17}$$

In the force balance of the plug flow (Eq. 16) the surface forces also can be expressed by the measured capillary pressure of the centrifuge cake (Eq. 18). This approach decouples the hydrodynamic properties of the hydraulic diameter from its effect on the surface force. The decoupling becomes more and more necessary the smaller the hydraulic diameter gets, because for fine particles the surface force calculated using the hydraulic diameter increases more than in the real cake.

$$\frac{1}{8 \cdot \lambda} = \frac{\Delta t \cdot \rho_\mathrm{L} \cdot g \cdot C \cdot d_\mathrm{h}^2}{32 \cdot \eta \cdot H} = \left(1 - \frac{x}{H}\right) - \frac{p_\mathrm{ke}}{\rho_\mathrm{L} \cdot g \cdot C \cdot H} \cdot \ln\left[\frac{\frac{x}{H} - \frac{p_\mathrm{ke}}{\rho_\mathrm{L} \cdot g \cdot C \cdot H}}{1 - \frac{p_\mathrm{ke}}{\rho_\mathrm{L} \cdot g \cdot C \cdot H}}\right] \tag{18}$$

The calculation of the plug flow determines the moment when the single-phase flow of the pore liquid has reached the filter media. From then on the remaining pore liquid drains as surface or film flow in the capillaries of the cake.

The regime of film flow can be described by applying the Nusselt film theory of a liquid film draining down a vertical plate. Finally, the saturation within the pores of the cake can be expressed with the same kinetic parameter λ introduced for plug flow (Eq. 17). The film saturation can be written as a power law with two optional parameters *a* and *b* (Eq. 19). The rigorous solution for a smooth and even surface quantifies *a* to 4/3 and *b* to 1/2. Usually *b* is a product parameter and it depends on the particle size distribution and the roughness of the particles. Therefore the numerical value of *b* after fitting to experimental data can vary in the range from 0.27 to 0.6.

$$S_\mathrm{F} = a \cdot \lambda^b \tag{19}$$

The time-dependent saturation of the centrifuge is calculated by a combination of both approaches. The overall saturation consists of three contributions: the mechanically nonremovable liquid, the film flow, and the plug flow (Eq. 20, Fig. 7). The nonremovable liquid consists of the liquid bridges, the adsorbed liquid, and the liquid located in inner porosity. The nonremovable saturation S_non amounts to 0.06 to 0.09 for smooth spheres. A typical value of S_non for mineral products is about 0.15.

$$S(t) = S_\mathrm{non} + \left(1 - S_\mathrm{non}\right) \cdot \left[\frac{x(t)}{H} + \left(1 - \frac{x(t)}{H}\right) \cdot S_\mathrm{F}\right] \tag{20}$$

Figure 7. Characteristic time-dependent desaturation; superposition of film and plug flow

a) Maximum saturation *S* = 1; b) Plug flow *S*(*t*); c) Film flow *S*(*t*); d) Superposition; e) Equilibrium saturation

An alternative approach to calculate the time-dependent dewatering of the cake uses the pore size distribution [5], [6], which is given by a capillary pressure curve. In all classes of capillaries the plug flow is calculated, without any contribution of the film flow. But the pore size distribution is not given in most practical problems, and therefore it is difficult to apply this model.

[Top of Page]

3. Discontinuous Filtering Centrifuges

The process integration of discontinuous centrifuges aims at processes which are operated batchwise. Semicontinuous operation is possible when several discontinuous centrifuges are combined. The maximum throughput of discontinuous centrifuges is 5–10 t_solids per hour. The maximal basket diameter of discontinuous centrifuges is about 2000 mm. The common size of discontinuous filtering centrifuges ranges from 600 to 1500 mm. The maximum centrifugal number is 2000, and the typical operating range *C* = 600–1500.

3.1. Cycle of the Discontinuous Centrifugation Process

Discontinuous centrifuges are operated batchwise. The process steps are executed in succession (Fig. 8). First the centrifuge is accelerated, and then the suspension is fed into the basket. It depends on the filtration properties, the concentration of the suspension, and the throughput whether more than one filling step is necessary. The rotational speed during the filling process is lower than the maximum speed, because usually the drive is not designed for the maximum drive torque, which occurs during the acceleration of the suspension.

After the cake has built up, the centrifuge basket can be accelerated to operational speed. The next steps are one or more washing steps, if required. After the last washing step desaturation (plug and film flow according to Eq. 19) occurs. Discontinuous centrifuges do not have technical restrictions on the residence time. Desaturation can be continued until saturation has reached equilibrium or the Bond saturation.

It depends on the type of discontinuous centrifuge at which rotational speed the basket is unloaded. Modern peeler centrifuges remove the cake at quite high rotational speed; the inverting filter centrifuge requires a low speed.

Figure 8. Cycle of discontinuous centrifugation

a) Acceleration of the basket; b) Feeding speed (≤ maximum speed); c) Acceleration to maximum speed; d) First washing step; e) Second washing step; f) Desaturation; g) Discharge at lower speed

3.2. Filling Strategies of the Centrifuge Drum

The cake formation process during filling depends on the ratio f_r of liquid fed to the basket and liquid consumed by the growing cake, either by being incorporated in the porosity or by passing through as filtrate flux. The filtration ratio can be approximated for suspensions of lower concentration by the ratio of liquid content of the feed suspension to the filtrate flux (Eq. 21). Here the liquid which fills the cake porosity is neglected.

$$fr = \frac{c_V \cdot \dot{V}_{susp}}{\dot{V}_L} \tag{21}$$

The right filling strategy must be developed to meet the requirements of the centrifuge. If the feed flux is too small, instant filtration occurs when the suspension hits the filter medium or the surface of the filter cake. In this case there is no smoothening effect of a liquid pool above the growing cake. The cake is formed where the suspension hits the surface and becomes more and more uneven, which leads to an imbalance in the basket rotation. The uneven cake height (Fig. 9) negatively affects the washing step, because the washing liquid drains through the thinner areas of the cake. The integral degree of impurity increases.

Figure 9. Regimes of cake formation as a function of feed flux

a) Optimal range of operation with minimal liquid pool; b) Low feed flux and instantaneous cake formation; c) Imbalance due to irregular cake formation; d) High feed flux and increasing pool depth; e) Imbalance due to liquid waves at the pool surface

High suspension feed rates lead to a high liquid pool above the cake, which increases the sedimentation distance of the particles. During sedimentation segregation can occur. Due to this segregation a heterogeneous cake with a higher resistance and a skin layer is formed, and this also has negative effects on the residence time and the desaturation properties. The skin layer increases the capillary entry pressure of the cake. Fine products showing this tight skin may even not be able to be desaturated in the centrifuge.

The optimum feed rate of a discontinuous basket centrifuge must be chosen between these two boundaries. In conventional processes the feed rate is constant over the filling interval, but the cake permeability and hence the filtrate flux decreases (Eq. 7). Therefore, the higher the cake grows, the deeper the overlying liquid pool becomes. Modern approaches try to set up a control strategy based on the filtration and desaturation models [7] to regulate the feed flux.

3.3. Peeler/Scraper Centrifuge

The peeler centrifuge is the most widespread construction of discontinuous centrifuges. The name derives from the strategy to remove the solids from the basket. A scraper is used which immerges into the cake while the basket still is in rotation. This automatic discharge replaces the manual labor of the operator which formerly was necessary.

Cake removal with a scraper leaves a thin cake layer in the basket. This layer is characteristic for the centrifuge type. As a positive effect it prevents any particle transfer through the filter medium in the following filling step. However, the thin layer ages due to deep-bed filtration effects and therefore its resistance increases from cycle to cycle, which leads to longer and longer processing times. When the thin layer has reached a certain resistance it is manually removed.

With the focus on hygienic design and good manufacturing practice the thin layer is a severe problem. It must be removed after each centrifugation step to prevent, e.g., any cross-contamination of separate batches.

Several concepts to remove the ground layer are available. The layer can be removed with mechanical, pneumatic, or hydraulic devices. The pneumatic concept either is operated with a strong air blow from the housing through the basket or

directly with an additional nozzle holder inside. The hydraulic concept feeds a larger quantity of liquid into the basket after scraping is finished. The ground layer is resuspended and flushed out off the basket. Any further cleaning uses the CIP (cleaning in place) equipment.

3.3.1. *Horizontal Construction*

The basket is mounted on a horizontal shaft, supported by fixed bearings. At the opposite side the shaft is powered by an electric drive via a V-belt. The basket is perforated and equipped with drainage media and a filtration medium above it. The front side can be closed with a door. An alternative concept uses a traversable housing, which can be removed to provide access to the entire basket and the internals.

Figure 10. Peeler centrifuge, in feeding mode (left) and discharge mode (right)

a) Shaft; b) Drive of transport screw; c) Feeding pipe; d) Washing pipe; e) Centrifuge lid; f) CIP nozzle; g) Centrifuge cake in the basket; h) Housing; i) Scraper during peeling of the cake; j) Transport chute; k) Solids discharge; l) Remaining thin layer

The feed piping reaches into the basket, and a special distribution device is mounted at its end (Fig. 10). The discharge scraper and the wash pipes are also located inside the basket. The discharge scraper feeds the solid to a funnel which is connected either to a chute or a transport screw. During filling, washing, and filtration the discharge unit is turned toward the inside of the basket.

Cake washing uses wash pipes or nozzles to achieve uniform distribution of the wash liquid over the cake surface. The flux of the injected wash liquid is high enough to create a liquid pool above the cake, which slowly drains through the cake.

3.3.2. *Vertical Construction; Three-Column Centrifuge*

The vertical peeler centrifuge consists of a vertically mounted basket in which the drainage and filter media are fixed. All feed pipes pass through the lid of the centrifuge. Directly after cutting, the solids are transported either upward with a pneumatic conveyer or fall down through the backplane of the basket into a chute.

To reduce vibration the vertical centrifuge is fixed on a massive frame or plate which lies on rubber dampers. An alternative concept is the three-column centrifuge. The basket and the drive unit are mounted as a kind of pendulum on three support points. This concept reduces the vibrations transferred to the ground.

3.3.3. *Siphon Centrifuge*

The siphon centrifuge is a modified horizontal peeler centrifuge in which a siphon is connected to the filtrate piping. Due to the hydraulic contact from the pore liquid through the filter medium into the filtrate in the siphon a hydrostatic pressure is built up. This suction is an additional driving force which accelerates drainage during cake formation, washing, and the plug-flow phase of desaturation. At the moment when the surface of the plug reaches the filter medium the hydraulic contact breaks and the suction force becomes zero.

The siphon also allows backflushing of filtrate into the basket, which can be used to regenerate the ground layer. The efficiency of the siphon can directly be controlled by the position of the skimmer tube (Fig. 11). It can be of advantage to start the suction force after the feeding of the basket, because a high filtrate flux at the beginning of cake formation favors formation of an uneven surface.

Figure 11. Principle of the siphon centrifuge

a) Skimmer tube; b) Hydraulic height; c) Siphon; d) Filter media

3.4. Inverting Filter Centrifuge

The inverting filter centrifuge is a specialized horizontal centrifuge (Fig. 12), which is used in integrated processing of high-quality products. The basket is mounted on the horizontal shaft. The basket can be closed pressure-tight with a special lid. The lid is connected by six anchors to the backplane of the basket. During the opening of the basket the connected front- and backplanes are shifted to the discharge side. The filter medium, which is fixed at the backplane and at the front edge of the basket, is inverted. After the inversion (Fig. 13) the inner side, on which the cake has been processed, has been turned outside. With a small acceleration the cake detaches from the filter medium into the housing and the discharge chute.

Due to the pressure-tight construction of the basket the inverting filter centrifuge also can be operated as hyperbaric centrifuge. The feed pipe, which is inserted from the front side though the lid, can be sealed with special membrane. The feed pipe is the only pipe which reaches into the basket; it is therefore also used to inject the washing fluid, as well as pressurized air during hyperbaric processing.

Figure 13. The inverting filter centrifuge — solids discharge

a) Feeding pipe; b) Shifted front- and backplane units; c) Removed centrifuge cake; d) Perforated basket; e) Housing and discharge chute; f) Shifted shaft

3.5. Centrifugal Dryer

The centrifugal dryer is a horizontal discontinuous centrifuge. The perforated basket is equipped with a fixed multilayer sintered metal sieve which has a minimum pore size down to 1 µm. The suspension is fed via the hollow shaft to the basket. The basket itself can be closed by a lid. The closed basket is pressure-tight up to 4.5–6 bar depending on the basket diameter. The centrifuge either is run with high rotational speed to perform centrifugal dewatering or with low speed to conduct the drying step. During the drying step air is blown through the metal sieve into the basket and the solids cake is fluidized. The product is retrieved from the basket through a connection to a pneumatic conveying system. To use this system the dry product requires excellent free-flowing properties. The centrifugal dryer is also able to perform solids washing. The washing liquid is injected through the hollow shaft.

[Top of Page]

4. Filtering Centrifuges with Continuous Feed

4.1. Conical Screen Centrifuge

Characteristic of the conical screen centrifuge is the conical basket. The suspension is fed through a nonrotating pipe to the smaller diameter of the basket. Due to the component of gravitational force parallel to the screen the solids cake is transported toward the larger basket diameter, where the discharge is located. Therefore, transport in the centrifuge depends on the slope of the conical basket and the interaction of the screen surface with the cake. At high friction between product and screen, blocking can occur.

The conical screen without any transport devices is characteristic for this centrifuge type. The lack of transporting devices allows quite high centrifugal numbers *C* of up to 3300 [1] but is also the largest disadvantage of the conical screen centrifuge, because the operator has no possibility to influence the residence time and the solids distribution in the basket.

Two constructional concepts are available for conical screen centrifuges: horizontal shaft and vertical shaft. The latter usually transport the cake upwards against gravity. The conical screen centrifuge is common in the raw sugar industry.

4.2. Vibrating Conical Screen Centrifuge

The vibrating conical screen centrifuge superimposes vibration of the basket to control and to improve the solids transport. The vibration is normal to the centrifuge axis. Therefore, the vibrating conical screen centrifuge is limited in its rotational speed because of the mechanical stress on the bearing and the shaft. Usually this centrifuge type is operated up to centrifugal numbers *C* of 120–150.

Due to this low centrifugal force only coarse products (e.g., in the mining industry) are processed with the vibrating conical screen centrifuge. The vibration can be controlled in amplitude and frequency to adjust the residence time and the product distribution in the basket.

4.3. Tumbler Centrifuge

The tumbler centrifuge superimposes a tumbling movement of the basket to improve solids transport. The tumbler centrifuge has a vertical shaft. The solids cake is transported upwards by the component of gravitational force parallel to the screen and by the revolving tumbling of the basket [8], [9]. The cake advances stepwise toward the discharge because of the quite low frequency of tumbling. The centrifugal number *C* ranges from about 150 to 300–400. The typical residence time is 5–10 s. Due to the quite high residence time and the controllable transport of the cake, washing is possible. Compared to the conical screen centrifuge the cake thickness is higher.

Tumbler centrifuges have been commonly used in the mining industry and in processing of coarse crystals.

4.4. Screen Scroll Centrifuge

The conical basket of a screen centrifuge is equipped with a conical screw to control solids transport, cake distribution, and cake thickness. This helical screw conveyor or a set of helical blades primarily transports the solids cake forward to the discharge side. The screw is operated with a differential rotation speed, which can be set up by a cyclo gear or a gearbox [3].

The screen scroll centrifuge is constructed either with vertical or horizontal shaft. The advantage of the vertical concept is

easy demounting, but the accessibility of the components during maintenance is poor. Today the horizontal concept is favored. The centrifuge either uses screens similar to the pusher centrifuge or laser-perforated plates [10]. The holes (80 µm to 1 mm) in these plates allow the processing of even finer products compared to the use of conventional screens. The void area of a typical wedge-wire screen is 4–10 % overall.

Due to the inclination α = 10–20°) of the basket [2] the solid cake slides down the screen. The screw controls this movement and with it the residence time (Eq. 22)

$$t_{res} = \frac{1}{\Delta n} \cdot \frac{L_{dr}}{H_{fl} \cos \alpha} \tag{22}$$

where H_{fl} is the flank lead of the screw, and Δn the differential speed of screw and basket. The gap between screw and basket must be quite small to prevent solids accumulation on the screen. A small gap also ensures better sealing when suspensions of low concentration are processed.

The screen scroll centrifuge has limited washing capacity. The washing liquid must be sprayed from the inside of the transport screw through holes or washing nozzles onto the solids cake.

The basket has two main functions: Near the inner diameter the basket is used as a thickening zone. Here a large quantity of liquid drains through the screen and the cake is about to be built up. Due to the ongoing concentration process the solids particles are mobile and the filtrate flux is able to transport them through the screen gap. In this part of the centrifuge the solids content in the filtrate is high.

The area close to the discharge side is used for cake dewatering, which is described by piston and film flow (Eq. 20). Due to the quite large particle diameter the efficiency of film flow is poor. The cake height is not constant within the spiral of the transport screw, but an average cake height (Eq. 23) can be calculated:

$$H = \frac{m_S t_{res}}{\rho_S (1 - \varepsilon) A_{scr}} \tag{23}$$

4.5. Pusher Centrifuge

The conventional concept of a pusher centrifuge is the horizontal machine (Fig. 14). The housing is divided into the filtrate-collecting zone and the solids discharge. The pusher centrifuge is fed from the front side. Usually the stationary tubing reaches into the drum. The suspension is fed into the drum, and in most cases an accelerating device (chamber, cone, or disk) is used. The centrifuge is fed continuously with a constant suspension flux.

The drum itself consists of a rotating perforated basket equipped with a wedge-wire screen. At the solids discharge the drum is open; at the opposite side it is connected to the hollow drive shaft. The pusher plate is located opposite to the discharge side; it acts as a backplane of the process chamber. It is mounted on its own shaft and rotates with the same speed as the basket. Additionally, the pusher plate undergoes a cyclic horizontal movement at a frequency of about 1 Hz.

The suspension is injected in the annulus which is formed by the amplitude of the pusher plate. When the pusher plate retreats, the suspension directly hits the metal sieve. This is the maximum mechanical stress for the particles [11].

Figure 14. Single stage pusher centrifuge

a) Feeding pipe; b) Feed accelerator; c) Drainage zone; d) Washing pipe

The cyclic movement of the pusher plate initiates horizontal cake transport. The centrifugal cake slides over the metal sieves of the drum. An annulus of the cake is discharged when it is transported over the edge of the drum.

An electric motor is used to power the rotation of the drum. The cyclic movement of the pusher plate is either created by a hydraulic system or a crank lever. The hydraulic system is favored for larger machine size.

4.5.1. *Cake Conveyance — Transport Model*

The cyclic movement of the pusher plate can be divided into four phases: advancing and retreating of the pusher plate as well as front and rear dead center. For hydraulic pushing systems the advancing and retreating movement occurs with constant velocity. The position of the pusher plate influences cake formation and cake structure.

Figure 15. Stepwise cake buildup during one periodic movement of the pushing plate

A) Backstroke; B) Cake compression; C) Cake movement; D) Front dead center

a) Metal sieve; b) Cake; c) Cake built during backstroke; d) Feeding funnel; e) Pusher plate; f) Cake built during backstroke; g) Cake built at rear dead center; h) Cake built until cake movement begins; j) Cake build at front dead center

During the backstroke (Fig. 15) of the pusher plate and the change of direction at rear dead center a homogenous cake is formed. When the pusher plate advances the cake is compressed and sheared [12], but the cake still grows due to the

suspension feed at the same time. When the cake is high enough to withstand the mechanical stress the whole cake in the drum comes into movement. From that moment on the newly built cake is no longer compressed, and it moves together with the rest of the cake in the drum. The pushing force (Eq. 24) which must be imposed by the hydraulic system can be calculated from the shear stress of the cake while it slides over the sieve.

$$F_{\text{push}} = \tau_{\text{y}} \cdot 2 \cdot \pi \cdot R \cdot L \tag{24}$$

where

$$\tau_{\text{y}} = \mu \cdot \frac{\left[R^2 - (R-H)^2\right]}{2R} \cdot \rho_{\text{c}}\, gC \tag{25}$$

and for small cake heights ($R \gg H$):

$$\tau_{\text{y}} = \mu\, H \rho_{\text{c}}\, gC \tag{26}$$

The cake density (Eq. 27) is a function of the porosity and the degree of liquid saturation:

$$\rho_{\text{c}} = \rho_{\text{S}}\,(1-\varepsilon) + \rho_{\text{L}}\,\varepsilon\, S(t) \tag{27}$$

The compression of the cake during the forward movement of the pusher plate can be quantified with the conveying efficiency (Eq. 28), which is the ratio of the distance the cake is moving and the stroke of the pusher plate:

$$\xi = \frac{\Delta\, y_{\text{cake}}}{\Delta\, y_{\text{stroke}}} = \frac{\dot{V}_{\text{susp}} c_{\text{m,v}}}{\pi \left[R^2 - (R-H)^2\right] f_{\text{push}}\, \Delta\, y_{\text{stroke}}} \tag{28}$$

for $\xi < 0.85$.

Using a mass balance allows the conveying efficiency to be written as a function of the feed flow of suspension. The concentration $c_{\text{m,v}}$ (Eq. 29) can be determined from a sedimentation experiment or calculated from the concentration c_{m}:

$$c_{\text{m,v}} = \frac{1}{\left[\left(\frac{1}{c_{\text{m}}-1}\right)\frac{\rho_{\text{S}}}{\rho_{\text{L}}} + 1\right](1-\varepsilon)} \tag{29}$$

The maximum conveying efficiency is about 0.8–0.9, so a good approximation for the maximum conveying efficiency is 0.85. Therefore, at low suspension feed rate the conveying efficiency increases with increasing feed rate and the cake height remains constant (Fig. 16). The constant cake height is called the natural cake height. When the maximum conveying efficiency has been reached the cake height in the centrifuge starts to increase and the conveying efficiency remains at a constant value of about 0.85.

Figure 16. Cake height as a function of feed rate

a) Natural cake height; b) Increasing cake height; c) Transition zone

Simplifying the cake geometry ($H \ll R$) allows the cake height to be written as a function of the conveying efficiency:

$$H = \frac{\dot{V}_{\text{susp}} c_{\text{m,v}}}{2\,\pi\, R\, \Delta\, y_{\text{stroke}} f_{\text{push}}\, \xi} \tag{30}$$

A detailed approach to calculate the cake height from the mechanical properties of the centrifuge cake is available in the literature [1].

The solids throughput (Eq. 31) of a pusher centrifuge depends on the cake geometry, the conveying efficiency, and the pushing frequency.

$$\dot{m}_{\text{S}} = \pi \left[R^2 - (R-H)^2\right] \xi\, f_{\text{push}}\, \Delta\, y_{\text{stroke}}\, \rho_{\text{S}}\,(1-\varepsilon) \tag{31}$$

The calculation of residence time of the cake within the centrifuge is a central question concerning the dewatering and washing results (Eq. 32). Due to its conception the pusher centrifuge allows the longest residence time of all continuous filtering centrifuges, up to 15 s.

$$t_{\text{res}} = \frac{L}{\Delta\, y_{\text{stroke}}\, \xi} \cdot \frac{1}{f_{\text{push}}} \tag{32}$$

The residence time decreases with increasing conveying efficiency. At constant maximum conveying efficiency the residence time is constant (Eq. 33). This is the minimum residence time $t_{\text{res,min}}$ in the pusher centrifuge:

$$t_{\text{res,min}} = \frac{L}{\Delta\, y_{\text{stroke}} \cdot 0.85} \cdot \frac{1}{f_{\text{push}}} \tag{33}$$

The residence time in the pusher centrifuge usually is sufficient to reach approximately the Bond plateau when the centrifuge is operated with natural cake height and high residence time. When the pusher centrifuge is operated with increasing cake height the final residual moisture usually is above the equilibrium moisture indicated in the Bond diagram.

The residence time available for dewatering usually is shorter, because 30–50 % of the residence time available is needed to conduct the washing step.

4.5.2. *Washing on the Pusher Centrifuge*

Washing on continuous filtering centrifuges differs from that on discontinuous filtering centrifuges. The consumption of washing liquid is significantly lower; it amounts to 20–200 kg per tonne of dry solids. Therefore, the pore volume in the cake is not entirely filled with the washing liquid. The washing liquid drains as a film or surface flow at the particle surface.

The washing liquid is sprayed onto the cake surface through several nozzles mounted on a nozzle holder. For countercurrent washing (Fig. 17) more than one nozzle holder is required. The filtrate-collecting zone in the centrifuge body is divided into different zones. The filtrate from cake formation, the washing liquid of the first washing step, and the washing liquid of the second washing step are collected independently. The liquid of the second washing step can be recycled and sprayed onto the cake in the first washing stage.

Figure 17. Scheme of countercurrent washing on a two-stage pusher centrifuge

a) Fresh washing liquid; b) Pushing plate; c) Nozzles (fresh liquid); d) Nozzles (recycled liquid); e) Partitions in the centrifuge housing to collect the filtrate and washing liquid; f) Recycle loop of washing liquid; g) Discharge of washing liquid

Most centrifuge suppliers position the nozzle holder directly after the cake-formation zone. At this position the cake has its maximum moisture; the isolated liquid bridges within the cake are not yet formed. Therefore, most of the pore liquid is accessible to the washing liquid [4], [13]. The dryer the cake, the less efficient the washing liquid.

4.5.3. *Feeding — Danger of Basket Flooding*

Feeding of the pusher centrifuge must consider that a mechanically stable cake is required in the feeding zone at the pusher plate. The necessary stability can only be given when there is no liquid pool above the newly built cake. Therefore, the operation parameters, which are mainly the solids concentration and the feed rate, must be controlled; otherwise, basket flooding occurs. At low solids concentration in the suspension, more liquid is injected to the machine than can be transported through the filter cake. In case of high feed rate the cake thickness and hence the cake resistance increase and the liquid transport of the filtrate decreases. In both cases a liquid pool at the top of the cake in the feeding zone is formed. This liquid starts to flow at the top of the cake towards the discharge side. Due to erosion effects channeling occurs during this liquid flow. The liquid flow increases the deeper the channels get, because the fed suspension also starts to run off the feeding zone. These channels quickly become deeper, causing a maldistribution of the solid in the drum. Finally the centrifuge itself comes out of balance and has to be stopped. The effect is called flooding of a pusher centrifuge.

The maximum feed rate (Eq. 34) which avoids flooding can be calculated if the specific cake resistance or the permeability of the cake is known:

$$\dot{V}_{\mathrm{susp,max}} = \frac{1}{1 - c_{\mathrm{m,v}}} \cdot \frac{\rho_{\mathrm{L}}\, Cg2\, \pi\, R\, \xi\, \Delta\, y_{\mathrm{stroke}}}{\eta_{\mathrm{L}}\, r_{\mathrm{c}}} \tag{34}$$

It can be concluded that the higher the solids concentration in the feed is, the more suspension can be fed into the pusher centrifuge. At high solids concentrations the pusher centrifuge has a high throughput. Therefore pusher centrifuges often are installed in combination with a thickening device (thickener, hydrocyclone, drum filter, DSM screen).

4.5.4. *Multistage Pusher Centrifuges*

The multistage conception has its main advantage in the reduction of the required pushing pressure. Most multistage pusher centrifuges are two-stage machines. The centrifuge drum consists of two concentric baskets. The inner basket conducts the cyclic horizontal movement. The backplane and the outer basket are fixed in the horizontal direction. The pushing force is transferred to the cake in the inner basket when the inner basket retreats. Then the wedge-wire sieve is pulled backwards under the cake, which is fixed by the contact to the stationary backplate. At the edge of the inner basket the annulus of cake falls in radial direction to the sieve of the outer basket. During the forward movement the cake in the inner basket is without motion relative to the sieve, but the front edge of the inner basket pushes the cake on the sieve of the outer basket toward the discharge side.

Figure 18. Concept of a two-stage pusher centrifuge

a) Feeding pipe; b) Feed accelerator; c) Cake buildup; d) Washing pipe; e) Cake at second stage; f) Cake discharge in chute; g) Hydraulic pushing system

The feeding of the multistage centrifuge occurs in the inner basket. The feeding conditions and calculations are similar to those of a single-stage centrifuge. Multistage centrifuges are less sensitive to flooding than single-stage machines, because the erosion of the cake stops at the transition to the next stage. Some three- or four-stage pusher centrifuges are

even operated in such a way that the inner basket is a thickening stage without cake formation. Nevertheless, multistage centrifuges usually also must be stopped when flooding occurs.

The pushing pressure and hence the size of the hydraulic system in the rotating hollow shaft are reduced by the two-stage conception, because of the smaller length of the cake to be transported. The pushing pressure is proportional up to the third power of the length of basket [1].

4.5.5. *Special Pusher Centrifuges*

The double-acting pusher centrifuge is a special construction with a single basket and a pushing plate in the middle position of the basket. It can be seen as a combination of two independent centrifuges in a back-to-back configuration. Both parts of the centrifuge use the same feed piping. The feed into each basket depends on the position of the pusher plate. The suspension is fed into that side of basket in which the pusher plate is in backward movement or at the backward dead center. This cyclic feed flow reduces the danger of flooding. Furthermore, the pushing plate is equipped with drainage holes through which any overlying liquid can drain to the opposite side of the basket, instead of flowing over the cake and provoking flooding. With this concept higher suspension throughput and robust operation are possible. The main disadvantages of the double-action pusher are the increased solids loss through the screen and the strong limitations in cake washing.

Pusher centrifuges, as well as conical screen centrifuges, vibrating conical screen centrifuges, and screen scroll centrifuges, use wedge-wire screens as filter media. Due to the sliding transport of the cake quite intense abrasion of the screens occurs. A second problem is sieve clogging when particles are clamped in the slot between two screen bridges. Therefore, the screen bridges are designed with a special shape. The slot widens from the cake side to the drainage basket side. This shape allows particles entering the screen slot not to be clamped, but to be transported with the filtrate. The widening at the screen slot is not constant. Near the cake side the gap has much less widening, and therefore after abrasion of the screen surface the slot width and hence the separation properties remain quite constant.

The wedge-wire screens usually consist of stainless steel and are manufactured by welding, milling, or multiple-turn coiling. The direction of the screen slots is parallel to the solids movement.

4.6. Decanting Centrifuge/Solid-Bowl Centrifuge

4.6.1. *Application for Filtration Dewatering*

Decanting centrifuges can be used for dewatering of coarse products (d_p > 50 µm) as well as for sedimentation (⟶ Centrifuges, Sedimenting). Their desaturation is a filtration process which occurs during transport of the sediment or cake in the conical part of the centrifuge. The cake is transported with the help of the screw uphill in the conical part of the solid bowl. The pore liquid drains due to the centrifugal force when the cake emerges from the liquid pool which fills the cylindrical part of the centrifuge. The residence time within the conical part of the machine is limited; it amounts to about 2 s. Because of the solid-bowl construction, the liquid flows along the bowl wall back to the pool. The limiting component of the dewatering capacity is the gap between screw and bowl.

4.6.2. *Dewatering Model*

In steady-state operation dewatering can be modeled with a simple, but efficient, approach [1]. The model is valid for coarse products, which easily reach the Bond plateau at the centrifugal values within the decanter. The model therefore does not take into account the filtration properties of the product itself. The mass balance (Eq. 35) around the control volume “conical part of the centrifuge” can be written as:

$$\dot{m}_{\mathrm{L},\uparrow} = \dot{m}_{\mathrm{L},\mathrm{R_M}} + \dot{m}_{\mathrm{L},\downarrow} = \dot{m}_{\mathrm{L},\downarrow} + \dot{m}_{\mathrm{S}} \cdot \frac{R_{\mathrm{M\,Bd}}}{1 - R_{\mathrm{M\,Bd}}} \tag{35}$$

where $\dot{m}_{\mathrm{L},\uparrow}$ is liquid transported uphill, $\dot{m}_{\mathrm{L},\downarrow}$ liquid flowing downhill in the conical part, and $\dot{m}_{\mathrm{L},\mathrm{R_M}}$ liquid adhering to solid $\dot{m}_{\mathrm{S}}$ forming the residual moisture R_{MBd}.

$$R_{\mathrm{M}} = \frac{m_{\mathrm{L}}}{m_{\mathrm{L}} + m_{\mathrm{S}}} = \frac{\dot{m}_{\mathrm{L}}}{\dot{m}_{\mathrm{L}} + \dot{m}_{\mathrm{S}}} \tag{36}$$

The liquid transported downhill can be expressed with the residual moisture (Eq. 36), where R_{Msat} is the moisture of the entirely saturated cake, when it enters the control volume (Eq. 37).

$$\dot{m}_{\mathrm{L},\downarrow} = \dot{m}_{\mathrm{S}} \cdot \left(\frac{R_{\mathrm{M_{sat}}}}{1 - R_{\mathrm{M_{sat}}}} - \frac{R_{\mathrm{M_{Bd}}}}{1 - R_{\mathrm{M_{Bd}}}} \right) \tag{37}$$

When the suspension (liquid and solid) throughput of the decanting centrifuge is increased the liquid flow downhill comes to its maximum. The maximal liquid flow (Eq. 38) can be assigned to critical solids throughput $\dot{m}_{\mathrm{S}}^{*}$. The maximal liquid flow can be written:

$$\dot{m}_{\mathrm{L},\downarrow}^{*} = \dot{m}_{\mathrm{S}}^{*} \cdot \left(\frac{R_{\mathrm{M_{sat}}}}{1 - R_{\mathrm{M_{sat}}}} - \frac{R_{\mathrm{M_{Bd}}}}{1 - R_{\mathrm{M_{Bd}}}} \right) \tag{38}$$

Any further increase of the throughput will increase the residual moisture in the solids discharge of the centrifuge. The liquid adhering to the solids in the case of $\dot{m}_{\mathrm{S}} > \dot{m}_{\mathrm{S}}^{*}$ is:

$$\dot{m}_{\mathrm{L},\mathrm{R_M}}^{*} = \dot{m}_{\mathrm{S}}^{*} \cdot \frac{R_{\mathrm{M_{Bd}}}}{1 - R_{\mathrm{M_{Bd}}}} + \left(\dot{m}_{\mathrm{S}} - \dot{m}_{\mathrm{S}}^{*} \right) \frac{R_{\mathrm{M_{sat}}}}{1 - R_{\mathrm{M_{sat}}}} \tag{39}$$

The moisture content produced by the decanting centrifuge is:

$$R_{\mathrm{M}} = R_{\mathrm{M_{Bd}}} \quad \text{when} \quad \dot{m}_{\mathrm{S}} < \dot{m}_{\mathrm{S}}^{*} \tag{40}$$

and

$$R_{\mathrm{M}} = \frac{\frac{R_{\mathrm{M_{Bd}}}}{1-R_{\mathrm{M_{Bd}}}} + \left(\frac{\dot{m}_{\mathrm{S}}}{\dot{m}_{\mathrm{S}}^{*}} - 1\right) \cdot \frac{R_{\mathrm{M_{sat}}}}{1-R_{\mathrm{M_{sat}}}}}{\frac{\dot{m}_{\mathrm{S}}}{\dot{m}_{\mathrm{S}}^{*}} + \frac{R_{\mathrm{M_{Bd}}}}{1-R_{\mathrm{M_{Bd}}}} + \left(\frac{\dot{m}_{\mathrm{S}}}{\dot{m}_{\mathrm{S}}^{*}} - 1\right) \cdot \frac{R_{\mathrm{M_{sat}}}}{1-R_{\mathrm{M_{sat}}}}} \tag{41}$$

when $\dot{m}_{\mathrm{S}} > \dot{m}_{\mathrm{S}}^{*}$

Figure 19 is a schematic plot of a typical chart and shows the constant moisture for solids throughput smaller than the critical throughput (Eq. 40). With further increasing solids throughput the moisture in the discharge steadily increases (Eq. 41). The critical solids throughput depends on the properties of the cake formed by sedimentation (porosity, equilibrium moisture at Bond plateau). This simple approach can be used for scale-up purposes [1].

Figure 19. Critical solids throughput

a) Minimum saturation at Bond plateau; b) Maximum saturation *S* = 1; c) Constant moisture content below critical throughput; d) Increasing moisture content; e) Critical throughput

4.7. Screen-Bowl Centrifuge

The screen-bowl centrifuge can be seen as a combination of a decanting centrifuge and a screen scroll centrifuge. It has a sedimenting section, where cake formation takes place. The cake, which is transported up the conical part of the decanting centrifuge enters the second process volume, a cylindrical basket equipped with metal screens. Both drum and basket are mounted in series on the same shaft. One screw ensures solids transport in both parts of the centrifuge. Decanter drum and basket are connected to each other and rotate at the same speed. The effective diameter of the basket is larger than that of the drum; therefore, the centrifugal number in the filtering part of the centrifuge is higher as well.

In the screen-bowl centrifuge the function of thickening and the function of filtering are separated; each is carried out in an individually optimized part of the centrifuge. Due to the higher residence time in the filtering part compared to a conventional decanter or screen scroll centrifuge the screen-bowl centrifuge has improved washing capacity. Due to its conception the filtrate and the used washing liquid can be collected separately, which simplifies recycling.

[Top of Page]

5. Hybrid Processes

Hybrid processes involving filtering centrifugation are mainly a combination of mechanical dewatering and thermal drying and aim at a dryer product with better handling properties. Some strategies line up several process steps, like the centrifugal dryer, which are conducted within the centrifuge basket. Real hybrid processes try to use the synergy effects which derive from the combination of mechanical and thermal effects.

5.1. Hyperbaric Centrifugation/Jet-Stream Centrifugation

The combination of gas differential pressure filtration and centrifugal filtration is called hyperbaric [14], [15] or jet-stream centrifugation. It can be operated in specially designed filtering centrifuges such as the siphon peeler centrifuge $(\Delta p_{\max} = 1\ \mathrm{bar})$ or the inverting filter centrifuge $(\Delta p_{\max} = 6\ \mathrm{bar})$. The additional driving force of the gas pressure or the vacuum accelerates liquid drainage during the plug-flow phase (Eq. 43). The gas pressure only slightly influences the film flow.

$$\dot{V} = \frac{\pi\, L_{\mathrm{dr}} [\, \rho_{\mathrm{L}}\ \omega^2\, (R^2 - r_{\mathrm{L}}{}^2) + 2\, \Delta\, p]}{\eta_{\mathrm{L}}\ r_{\mathrm{C}} \ln \frac{R}{r_{\mathrm{S}}}} \tag{42}$$

$$\frac{1}{8\,\lambda} = \frac{\Delta\, t\, \rho_{\mathrm{L}}\, g C d_{\mathrm{h}}{}^2}{32\, \eta\, H} = \left(1 - \frac{x}{H}\right) + \frac{\Delta\, p - p_{\mathrm{ke}}}{\rho_{\mathrm{L}}\, g C H} \cdot \ln \left[\frac{\frac{x}{H} + \frac{\Delta p - p_{\mathrm{ke}}}{\rho_{\mathrm{L}} g C H}}{1 + \frac{\Delta p - p_{\mathrm{ke}}}{\rho_{\mathrm{L}} g C H}}\right] \tag{43}$$

The superimposed gas pressure is an additive term in the known equations for dewatering kinetics using the kinetic parameter λ and the filtrate flux (Eq. 42).

The field of application of hyperbaric centrifugation primarily is in fine products, which show desaturation behavior in the Bond II regime. The gas pressure is applied to remove the remaining liquid in the capillaries near the filter medium. In this hybrid process the advantages of both processes are combined: solids handling and washing in the centrifugal field and the higher driving potential of the gas pressure.

5.2. Steam-Enhanced Centrifugation/Steam-Pressure Centrifugation

Instead of pressurized air, pressurized steam is used to build up the pressure difference. The process can be seen as a combination of steam-pressure filtration [16], [17] and centrifugal filtration. Steam filtration uses the positive effect of the self-stabilizing displacement front, which strongly reduces early gas breakthrough. The use of steam in steam-pressure filtration improves the dewatering result by about 20 % of saturation compared to conventional filtration with identical process parameters. Steam-enhanced centrifugation can be applied with two different strategies, either in the Bond II or in the Bond III region. In the Bond II region the pressurized steam is used for improved filtration of the remaining liquid in the capillaries. The moisture content is reduced and handling properties of the solids improved. The application of steam-enhanced centrifugation in Bond III under the condition that the saturation is less than 0.15 leads to an entirely dry product [18]. Mechanical separation and drying are performed simultaneously in same process volume. Steam-pressure centrifugation belongs to the mechanical-thermal dewatering processes.

The dewatering theory of conventional and hyperbaric centrifugation can be further extended to describe displacement with a condensable gas [19]. The plug flow is written with an energy parameter Ψ which contains the ratio of sensible to latent heat.

$$\frac{1}{8\,\lambda} = \frac{\Delta\, t\, \rho_L\, g C d_h^{\,2}}{32\, \eta\, H} = (1-\psi)\cdot\left(1-\frac{x}{H}\right) + \left[\psi - (1-\psi)\cdot\frac{\Delta\, p - p_{ke}}{\rho_L\, g C H}\right]\cdot \ln\left[\frac{\frac{x}{H}+\frac{\Delta p - p_{ke}}{\rho_L g C H}}{1+\frac{\Delta p - p_{ke}}{\rho_L g C H}}\right] \tag{44}$$

where

$$\psi = \frac{\eta_{st}}{\eta_L}\cdot\frac{c_{p,S}\,\rho_S\,\Delta\, T}{\rho_{st}\,\Delta\, h_v}\cdot\frac{1-\varepsilon}{\varepsilon} \tag{45}$$

The calculated breakthrough time (Eq. 44) is essential for economic operation of the process. Steam injection is efficient during plug flow until steam breakthrough. Any further steaming creates costs without any reduction in moisture.

The steam, which partly condenses within the pores of the cake, has a certain washing efficiency. Steaming can approximately replace an amount of washing liquid equal to the amount of condensate produced [20].

[Top of Page]

6. Laboratory-Scale Testing

The dimensioning of technical centrifugation processes requires laboratory- and pilot-scale testing. Since ca. 1995 the quality of the laboratory scale experiments and equipment has been improved. The main focus of laboratory-scale experiments is on desaturation kinetics and the equilibrium of dewatering (Bond diagram).

Effects of cake formation and cake structure require larger experimental setups because the movement of the liquid pool relative to the cake surface has a governing influence.

6.1. Laboratory Centrifuges

The standard laboratory-scale centrifuge is a bucket centrifuge with either vertical or horizontal shaft. The test bucket is filled outside of the centrifuge with a previously built cake or with suspension. The direct feeding of bucket centrifuge with suspension has the disadvantage that, due to the Coriolis force, an inclined cake surface is formed.

The acceleration time until maximum rotary speed is a criterion for division into high- and low-end laboratory-scale centrifuges. High-end laboratory centrifuges are necessary to follow the time-dependent processes within continuous centrifuges, which have a time frame of several seconds. During this interval the cake in the laboratory-scale centrifuge must be accelerated, processed, and decelerated. If an on-line sensor system is used, the deceleration is no longer relevant to the measurement.

The typical bucket concept applying an on-line sensor consists of a bucket with a filtering bottom (Fig. 20). The filtrate is collected below in a reservoir, which is equipped with a pressure sensor. This sensor has the function of a balance; it is able to quantify the mass of filtrate. The sensor signal is recorded either by telemetry, via a collector ring, or with help of a data logger. The typical acceleration time of high-end laboratory centrifuges is <thinsp;2 s. The typical centrifugal number *C* of a high-end laboratory centrifuge is about 4000 (up to 6000). With the help of structural information on the cake the time-dependent saturation can be calculated from the recorded function “filtrate mass over process time”.

Figure 20. Conception of a high-end lab scale centrifuge and bucket

a) Housing; b) Rotor; c) Shaft; d) Bucket inserted into the rotor; e) Cake built up in the bucket; f) Filtrate funnel; g) Reservoir with collected filtrate; h) Pressure sensor for on-line measurements

The low-end laboratory centrifuges are used to estimate the equilibrium of dewatering or Bond curve. The cake is processed for several minutes and the moisture content is measured off-line. This set of information can be sufficient for the design of discontinuous processes.

An alternative to the bucket centrifuge is the so-called ring centrifuge, which is a smaller basket centrifuge. The basket length is reduced to an annulus with an opening of several centimeters. The bottom of the ring can be equipped with either a metal sieve or a filter medium. This type of centrifuge requires a larger quantity of suspension. The main focus of the investigations is on cake formation and cake washing. On-line sampling of the filtrate is possible, but it shows a quite high dead time until the filtrate creates a signal on the balance.

[Top of Page]

7. Applications

The field of application is too wide to be discussed here. Application and process integration of filtering centrifuges are described under other keywords

pharmaceutical chemicals, bulk polymers (⟶ Polyolefins – Polypropylene, ⟶ Polymerization Processes – Polymerization Processes and Reactor Modeling), minerals (⟶ Potassium Compounds – Potassium Chloride, ⟶ Coal – Coal Preparation; ⟶ Sodium Sulfates), food (⟶ Sugar – Separation of Sugar from Massecuite), fibers (⟶ Paper and Pulp – Pulp), proteins (⟶ Starch – Starch), ores, bulk chemicals, fine chemicals and intermediate chemicals (⟶ Terephthalic Acid, Dimethyl Terephthalate, and Isophthalic Acid – Production; ⟶ Adipic Acid – Production), commodity chemicals (⟶ Laundry Detergents – Production of Powder Detergents), catalysts (⟶ Heterogeneous Catalysis and Solid Catalysts – Production of Heterogeneous Catalysts).

1. Introduction

Sedimenting centrifuges are used for the separation of two or three phases: liquid – liquid, liquid – solid and liquid – liquid – solid. Sedimenting centrifuges use centrifugal force to accelerate the sedimentation process. By rotating the process fluid, the sedimentation rate can be increased by a factor of several thousands compared to static sedimentation or settling. Other types of equipment also use centrifugal force for phase separation. This article deals only with sedimenting centrifuges. For filtration centrifuges and hydrocyclones, see → Hydrocyclones and → Centrifuges, Filtering.

In *liquid – liquid separation* the most common alternative to sedimenting centrifuges are static settlers. The advantage of the centrifugal separator compared to the settler is the small equipment volume and/or short residence time.

The choice between a centrifugal filter and a sedimenting centrifuge in *solid – liquid separation* depends on the particle size and the permeability of the cake of solids in the centrifugal field [17].

Cross-flow filtration may be an alternative to centrifugation for small particle sizes and mostly for small flow volumes.

2. Fundamentals

2.1. Centrifugal Sedimentation

General. The sedimentation rate of solid particles or droplets in the gravity field is a function of the particle (or droplet) size, the density difference, and the viscosity of the suspension (or emulsion). In applications in which centrifuges are used, the static sedimentation velocity is between 10^{-9} and 10^{-4} m/s. To accelerate the process, centrifuges apply centrifugal forces of 500 – 30 000 g.

At lower sedimentation rates, special ultracentrifuges with up to 900 000 g are used to separate macromolecules, virus particles, and microbial cell constituents. Sedimentation velocities are expressed as sedimentation coefficients in Svedberg units (S), have the dimension seconds, and are defined as 10^{13} times the settling velocity per unit acceleration (in m/s^2). They range from 4 to 10^6 S [5].

A third class of centrifugal separators are gas centrifuges, used primarily to separate isotopes (→ Isotopes, Natural, Chap. 4.2.3). Uranium enrichment is the best known application. The centrifugal force is greater than 150 000 g. The enrichment in a single centrifuge is very small, so a large number of machines have to be arranged in series to obtain a sufficient degree of enrichment.

Settling Velocity. The settling velocity of the particles or droplets is a fundamental property of a suspension or emulsion and determines the flow rate through or size of the centrifuge together with the residence time and settling length. In most centrifugations the settling velocity u_c is so small that Stokes law applies:

$$u_c = \frac{(\varrho_p - \varrho_l)\, d_p^2}{18\,\eta} \cdot r\,\omega^2 \ [\mathrm{m/s}] \tag{1}$$

where ϱ_p and ϱ_l are the densities of particle and surrounding medium, d_p is the particle diameter, η is the viscosity of the suspension, r is the distance from the center of rotation, and ω is the angular velocity, which is related to the bowl speed n in rpm according to the relation

$$\omega = \frac{2\,\pi\,n}{60} \ [\mathrm{s}^{-1}] \tag{2}$$

The acceleration factor Z (the g number) is

$$Z = \frac{r\,\omega^2}{g} \tag{3}$$

where g is the acceleration due to gravity. The settling velocity u_g in the gravity field is

$$u_g = u_c \cdot \frac{g}{r\,\omega^2} \ [\mathrm{s/m}] \tag{4}$$

The Equations (1) and (4) are valid under the conditions that

1) The flow round the particle is laminar (Reynolds number $Re < 0.4$)
2) The settling of a particle is not influenced by other particles, i.e., the concentration is very low

For particle $Re > 0.4$ alternative equations have been derived [2, 5]. For high particle concentrations, a phenomenon called hindered settling sets in, decreasing the settling rate. Equations for correction factors < 1 for the settling rates u_c and u_g in Equations (1) and (4) are summarized in [9]. At 20 vol % of particles, the settling rates decrease by a factor > 2.

Residence Time and Settling Length. A high g number (Z) is not the only factor that determines the flow rate at acceptable separation efficiency through a centrifuge. The residence time in the centrifugal force field, i.e., the rotor volume, can compensate for a small Z. A small settling length, i.e., the distance a particle must travel to sbe captured, will also improve the flow rate at acceptable separation efficiency.

The Bottle Centrifuge. The settling velocity of particles that are separated in a centrifuge is often so small that its measurement is not practical without application of centrifugal force. The bottle (swing-out) centrifuge, shown schematically in Figure 1, is often a suitable tool for measurement of the settling velocity.

Figure 1. Bottle swing-out centrifuge

The following equations describe the particle motion:

$$u_c = \frac{dr}{dt} \tag{5}$$

$$u_c = u_g \cdot \frac{r\,\omega^2}{g} \tag{6}$$

The aim is for all particles to move to a radius $> r_2$. In the worst case, the particle starts at the liquid surface at r_1. Insertion of Equation (6) into Equation (5), rearranging, and integrating gives

$$\int_0^T dt = \frac{g}{u_g\,\omega^2} \int_{r_2}^{r_1} \frac{dr}{r} \tag{7}$$

$$T = \frac{g}{u_g\,\omega^2} \cdot \ln \frac{r_2}{r_1} \tag{8}$$

where T is the spinning time necessary for all particles to leave the volume between levels r_1 and r_2. By rearranging Equation (8) one obtains

$$u_g = \frac{g}{T\,\omega^2} \cdot \ln \frac{r_2}{r_1} \tag{9}$$

It is clear that a small settling velocity necessitates a long spinning time, i.e., residence time, and/or a short sedimentation distance at a high angular velocity. This is also valid for centrifuges with continuous feed and effluent flow. Because of mechanical and hydraulic limitations, these requirements are in conflict with each other and can not be met in industrial centrifuges without compromises. This has led to the development of a broad range of machines in which different requirements have been given priority.

2.2. Centrifugal Sedimentation with Continuous Flow

The Σ Theory.

The Generalized Σ Formula. The most used quantity to characterize centrifuges, the Σ concept, was presented by Ambler [36, 37]. It is the calculated equivalent surface area of a static settling tank with the same theoretical performance. In its derivation he considered particles with a critical diameter d_c that were separated to 50 %. Today, however, the most widely used definition of the critical particle is that which is separated to 100 %. This does not influence the formulas for the Σ value, but the value for the feed flow rate Q is halved.

Σ is defined as

$$Q_{theor} = u_g\,\Sigma \tag{10}$$

where u_g is the Stokes settling velocity (Eq. 1). Σ is given by the general expression

$$\Sigma = \frac{V}{s_e} \cdot \frac{\omega^2 \cdot r_e}{g} \tag{11}$$

where V is the liquid volume in the bowl, s_e is the effective settling distance, and r_e is the effective distance from the center of rotation.

With Equations (1) and (4) the equation for the critical diameter becomes

$$d_c = \left(\frac{18\,\eta\,Q_{\text{theor}}}{(\varrho_p - \varrho_f)} \cdot \frac{s_e}{V \cdot \omega^2 \cdot r_e}\right)^{\frac{1}{2}} = \left(\frac{18\,\eta\,Q_{\text{theor}}}{\Sigma\,(\varrho_p - \varrho_f)\,g}\right)^{\frac{1}{2}} \tag{12}$$

The derivation above is based on the assumption that

- Viscous drag determines the particle movement
- The flow in disk bowls between the disks is laminar and symmetrical
- The liquid rotates at the same speed as the bowl
- The particle concentration is low (no hindered settling)
- The particle at all times moves with its final settling velocity u_c
- The settling velocity u_c is proportional to the g force.

Ambler uses the critical particle in his formula; therefore, his analysis is a special case of Svarovsky's grade efficiency function [7], in which for each particle size the ratio of sedimented mass to the mass in the feed material is determined and integrated over all particle sizes to give a more realistic measure of the separation efficiency. The terminology, definitions and theory of particle classification is dealt with comprehensively in [9].

Σ for Various Centrifuges. The flow system in between two conical disks in a disk-bowl centrifuge is shown in Figure 24. The particle has a radial velocity component u_c because of the centrifugal force, which increases with increasing r. It has also a drag dependent velocity component u_d which can have any size or direction depending on the flow situation round the particle. In the Σ theory it is assumed that it depends on uniform radial plug flow parallel to the disks. The derivation of the Σ for various types of centrifuge is found in [37], and the results are summarized in the following:

Disk-bowl [36, 37]

$$\frac{\pi \cdot \omega^2}{g} \cdot \frac{2}{3} \cdot N \cdot \left(r_2^3 - r_1^3\right) \cdot \cot\alpha$$

r_2 = max. radius of disk,
r_1 = min. radius of disk,
N = number of disk,
α = half-cone angle of disk

Decanter [7, 37]

$$\frac{\pi \cdot \omega^2}{g}\left[L_1\left(\frac{3}{2} \cdot r_2^2 + \frac{1}{2} \cdot r_1^2\right) + L_2\left(\frac{r_2^2 + 3\,r_2\,r_1 + 4\,r_1^2}{4}\right)\right]$$

L_1 = length of cylindrical part,
L_2 = length of conical part,
r_1 = inner radius of liquid,
r_2 = inner radius of bowl,

Tubular-bowl, chamber-bowl [37]

$$\frac{\pi \cdot \omega^2}{g}\,L\,\frac{r_2^2 - r_1^2}{\ln\left(\frac{2\,r_2^2}{r_2^2 + r_1^2}\right)}$$

r_1 = inner radius of liquid,
r_2 = inner radius of bowl,
L = inner length of bowl,

Multichamber-bowl [2]

$$\frac{\pi \cdot \omega^2}{g}\,\frac{L}{3}\sum_{i=0}^{i=n}\frac{r_{2\,i+1}^3 - r_{2\,i+2}^3}{r_{2\,i+1} - r_{2\,i+2}}$$

indices with even numbers = inner radius of chamber,
indices with odd numbers = outer radius of chamber,
$n + 1$ = number of chambers,
L = height of chambers

Separation Efficiency. The assumptions in the Σ theory are not fulfilled in reality. Therefore, Equation (10) should include an efficiency factor μ, so that in practice the flow rate is lowered for the required separation performance. Estimated efficiency factors are listed in the following [6]:

Disk-bowl machines	45 – 73 %
Decanter centrifuges	54 – 67 %
Tubular bowls	90 – 98 %

By careful measurement of the density difference and particle dimensions in one case an efficiency factor of max. 16 % was found to fit the experimental data in a pilot-scale disk bowl machine [38]. However, this probably also included effects of hindered settling.

In the absence of hindered settling, the equation describing the relationship between the feed flow rate, the Σ value, and the settling rate, is thus

$$Q_{\mathrm{act}} = \mu\, u_{\mathrm{g}}\, \Sigma \tag{13}$$

The KQ Formula for Disk-Bowl Centrifuges. A semi-empirical equation for the "separation area" [39] is based on the finding that separation data fit the relation

$$\frac{u_{\mathrm{c}}}{u_{\mathrm{g}}} = \left(\frac{\omega^2\, r}{g}\right)^k \tag{14}$$

with $k = 0.75$ better than the classical analysis (Eq. 4) with $k = 1$. This is a consequence of the increasing shear forces in the Ekman layers (see Section 5.2). For practical purposes the following relation is used:

$$\mathrm{KQ} = 280 \cdot \left(\frac{n}{1000}\right)^{1.5} \cdot N \cot\alpha\, \left(r_{\mathrm{out}}^{2.75} - r_{\mathrm{in}}^{2.75}\right) \tag{15}$$

where n is the bowl speed in rpm and r_{out} and r_{in} are the radii of the disk in centimeters. This form of the KQ formula is dimensionally incorrect, but it is mathematically possible to make it correct and to express the KQ value as an entity with the dimension of area. In practice the difference between KQ and Σ for scale-up purposes is negligible, compared to other inaccuracies.

Hindered Settling. One of the few experimental investigations into hindered settling of cells [38] shows that complex phenomena occur at high concentrations. A model with several experimental constants was developed. It showed that settling rates decrease rapidly with increasing solids contents, by a factor of about 2 at 20 vol % and by 15 – 20 at 50 vol %. The classical model used in [39] gave similar results. The decreased settling velocity can be attributed to increased viscosity of the suspension at high solids concentrations [9]. In the tests in [38] it was also found that cells may settle as flocs at higher concentration. Hindered settling is one further example of the difficulty to calculate theoretically the performance of centrifuges.

Gas Centrifuges. The theory for gas centrifugation is too complicated to be included here. The performance of a gas centrifuge is, besides peripheral velocity and rotor length, very much depending on the flow pattern in the rotor and the location of entry and exit points of the streams. The reader is referred to [5] and [13].

3. Centrifugal Separators with Continuous Feed

3.1. General

The different types of continuous centrifuge were developed from different principles of solids handling. The first centrifuges were developed for separating a process fluid (e.g., milk, fermented yeast broth) into two fluid streams. Heavy solids that could not flow out were collected at the periphery and removed by periodic manual cleaning. These were followed by centrifuges with peripheral nozzles that discharge solids as a slurry. In many processes these replaced machines needing expensive manual cleaning. For processes in which the solids must be collected in a more concentrated, nonfluid, form, machines with internal conveyors (decanter centrifuges) were developed. Intermittently discharging machines were developed to fill the gap between the three above-mentioned types and are now the most common continuous centrifuges. A number of discharging mechanisms have been developed over the years. A bottle centrifuge with continuous feed and separated effluent (centrate) is available.

The most comprehensive description of centrifuges can be found in [2]. Brochures and technical publications from centrifuge manufacturers provide the most modern information about machine types, sizes, and capacities.

3.2. Disk-Bowl Machines

General. In disk-bowl machines the sedimentation path is made short by introduction of conical discs, separated by spacers. The distance is between 0.4 and 3 mm, depending on the viscosity and solids content. The half-cone angle is in the range 35 – 45° and is smaller for solids with a small angle of repose.

The spacers between the disks have different designs, depending on the separation duty. The most common spacers are long ribs placed radially along the cone; these help the liquid retain its rotation velocity. The majority of disk-bowl machines are used for separating two liquid phases. In many cases, droplets of the dispersed phase in the feed liquid coalesce atan interface inside the bowl, and the newly formed liquid leavesthe

bowl continuously through a second outlet, separated from the original continuous phase. The position of the interface in the bowl is important and can be controlled by, for example, adjusting the radius of one of the weirs, usually that for the heavy phase. Its radius r_h (see Fig. 2) is given by

$$r_h = \sqrt{r_i^2 \left(1 - \frac{\varrho_l}{\varrho_h}\right) + r_l^2 \cdot \frac{\varrho_l}{\varrho_h}} \tag{16}$$

where r_i is the radius of the interface, r_l the outlet radius of the light liquid phase, and ϱ_l and ϱ_h are the densities of the light and heavy liquid phases. The equation is derived from a pressure balance but is a simplification because it neglects pressure drops and weir heights. It is adequate for a first approximation. It is also applicable to chamber bowls, tube centrifuges and decanters (Sections 3.3, 3.4 and 3.5).

If the objective of the separation is to obtain a very clean light phase, the interface should be placed at a large radius to avoid heavy droplets' contaminating the light phase. For obtaining a clean heavy phase, the interface should have a small radius.

Several important applications of liquid – liquid separations in disk bowls do not involve coalescence at an interface. The most common examples are separation of cream from milk and alkali refining of vegetable oil. The split between the outlet streams is then controlled by counterpressures that can be applied in several ways.

Solid-Bowl Centrifuge. Figure 2 shows a solid-bowl centrifuge requiring manual cleaning. Heavy solids are collected at the periphery; the machine must be dismantled and the bowl opened to remove the solids, often by lifting up a collecting basket, fitted inside the bowl. The feed enters the bowl in the center through a still-standing pipe. The version of bowl shown is suitable for liquid – liquid – solid separation and therefore has two liquid outlets. The light liquid flows through the disk stack and out of the bowl through a still-standing centripetal pump known as a paring disk. The heavy liquid passes over a disk near the bowl hood and is removed through another paring disk. The paring disk converts the kinetic energy of the rotating liquid, and discharges it under pressure.

Figure 2. Solid bowl with disks, requiring manual removal of solids (vertical section)

This type of bowl has diameters between 140 and 750 mm. The solids space has a volume of up to 34 L. Further data are listed in Table 1. The principles illustrated in Figure 2 are also applicable to other bowl types. Instead of paring disk(s), open outlets over weirs can be used. In many cases only one of the two outlets has a paring disk.

A small solid-bowl machine is shown in Figure 3.

Figure 3. A small solid-bowl centrifuge (type Emmie; courtesy Alfa Laval Separation AB)
The bowl diameter is 140 mm.

Table 1. Characteristics of continuous-feed centrifuges [a]

Type	Mode of solids discharge	Feed flow rate, L/h	Feed solids content, vol %	Solids flow rate, L/h	Σ value, m^2	Max. Z developed	Consistency of solids

[a] Low-speed imperforate tubular and basket machines not included.
[b] Only for slurry of single cells (see text).
[c] Only for mammalian cells.

This type of machine was recently introduced for cleaning of crank-case gas in truck diesel engines. Oil droplets and soot particles are separated. The unit is driven by pressurized oil from the engine lube oil flow [3].

Solids-ejecting separators are the most common disk-bowl centrifuges. Automated intermittent discharge of the separated solids accumulated at the periphery allows relatively high concentrations to be obtained in the discharged solids. The rheology of the solids is very important for successful application of this type of machine. Dilatant solids such as starch cannot be discharged; the most suitable materials are noncrystalline solids of biological origin. Mixed solids can often be discharged but may require that a large amount of liquid is discharged together with the solids and/or that the residence time of the solids in the bowl is short, thus avoiding the formation of excessively hard packed solids.

Figure 4 shows a solids-ejecting bowl. The discharge takes place in about 0.1 s by lowering a hydraulically operated slide at the bottom of the bowl to release solids through ports in the bowl body.

This is illustrated in a video clip.

Figure 4. Radially solids-ejecting disk bowl, top feed (vertical section)

The version of bowl shown is equipped with a sensing chamber, which senses the level of solids in the bowl and triggers a discharge when the solids space is full. The solids space is designed so that solids can slide easily towards the opening. For solids with good flow properties, the angles between the solids space wall and the axis of rotation can be made smaller and hence

the outer diameter of the disks larger, increasing the separation area.

In applications where the particles in the feed material are easily broken up by the shear forces in the inlet, machines with feed from below through a hollow spindle are commonly used. In this case the bowl is filled with liquid into the center. For liquid – liquid separation, the split between the flows can be made by controlling the pressure applied on the exiting liquids. Solid-bowl machines are also available with this system.

Solids-ejecting bowls are made with diameters ranging from 180 to 1000 mm, (Figs. 5, 6, and 7). For further data, see Table 1.

Figure 5. Solids-ejecting disk-bowl centrifuge of pilot size for sterilizable contained installation (type Culturefuge 100; courtesy Alfa Laval Separation AB)
The separator itself is 1.3 m in height.

Another design of an intermittent discharge system is shown in Figure 10 where it is used as cleaning system for a nozzle machine. It is also available on its own and is suitable for discharging solids with very good flow properties, e.g., proteins and microorganisms. Solids are discharged from a number of peripheral axial channels, which are opened by lowering a slide with valve seats. The valve slide operates by allowing pressurized air to enter the volume between the bowl bottom and the slide. Models with a hydraulic discharge system are also available. Bowls with diameters of between 530 and 900 mm are currently in production. The machines have high speeds and high *g* forces (Table 1).

Figure 6. Solids-ejecting disk-bowl centrifuge for medium-scale production and explosion-protected and inerted installation (type CHPX 510; courtesy Alfa Laval Separation AB)
The height of the separator is 1.4 m. In the foreground is a liquid seal tank.

Figure 7. Solids-ejecting disk- bowl centrifuge of a large production size (type CHPX 517; courtesy Alfa Laval Separation AB)
Hydraulic capacity 40 m^3/h. The height of the separator is 1.7 m.

Nozzle Machines. When the solids flow rate is too large or the solids rheology unsuitable for the solids-ejecting machines, peripheral nozzle machines are used (Fig. 8). A possible alternative to nozzle machines are decanters, but the separation area of these is more than an order of magnitude smaller, and they are therefore used when the separability of the solids is better. The number of nozzles increases with increasing bowl size and ranges from 4 to 20. The nozzle diameter ranges from 0.5 to 3.5 mm.

The approximate flow Q_N through nozzles in nozzle machines can be calculated from the formula

$$Q_N \approx k\, a_N\, r_N\, \omega\, z \;\; [\mathrm{m}^3/\mathrm{s}] \tag{17}$$

where a_N is the nozzle area, r_N the distance of nozzle from center of rotation, ω the bowl speed in rad/s, z the number of nozzles, and k is a proportionality constant ($k \approx 0.83$) (all quantities in SI units). The nozzle flow is proportional both to the radius and to the bowl speed.

Some bowls are equipped with a central feed tube for recirculated solids. These solids are introduced in front of the nozzles, bypassing the disk stack, thereby avoiding disturbances to the separation process. The recycle stream is used to increase the solids concentration when insufficient solids are present in the feed to fill the smallest possible nozzles. Small nozzles have a larger tendency to be clogged by oversize particles in the feed. Many nozzle machines are used without recirculation of solids, and the same bowl can be used but without the recycle components. In a third variant, the concentrate tubes can be used to feed wash water to the nozzles from the central chamber, which is supplied with water through a hollow bowl spindle.

Figure 8. Nozzle bowl with peripheral discharge nozzles and recirculation of solids (vertical section)

Figure 9. A nozzle machine type TX 320 with peripheral nozzles installed in a starch factory (courtesy Alfa Laval Separation AB)
Hydraulic capacity 200 m^3/h. The height of the machine is 2.2 m.

Figure 10. Nozzle bowl with pressurized nozzle discharge and slide for Cleaning-in-Place (CIP) (vertical section)

Peripheral nozzle sedimenting centrifuges are suitable for the largest flow rates (see Table 1), and the bowls can have a diameter of up to ca. 1000 mm. A large nozzle machine of this type is shown in Figure 9.

With pseudoplastic solids having an angle of repose of 0° (e.g., yeasts and bacteria), the solids concentrate is taken from the periphery in a number of tubes (Fig. 10) into a chamber in which it is taken up by a nonrotating paring tube, which pumps it up and out through a central pipe. In front of the nozzles, vortex chambers can be mounted. The concentrate enters these tangentially and creates a whirl which acts as a resistance to flow over the chamber. With high-viscosity concentrate, the speed of the whirl is small, the flow resistance is low, and flow through the system is high. At low viscosity, the flow is higher. The viscosity effect gives rise to a self-regulatory function, so that with variable solids flow (within limits) into the machine, the resulting concentration in the solids concentrate is constant. The risk of clogging the machine is reduced. In machines without vortex chambers, the concentrate tubes can be replaced by channels in the bowl body. These channels start at the periphery of the bowl, are directed towards the center of rotation, and end with nozzles at the bottom of the bowl, spraying out the concentrate under the bowl.

Figure 11. Nozzle machine with pressurized solids discharge for yeast and bacteria separation. Capacity for *E. coli* bacteria about 3000 L/h (type BTUX 510; courtesy Alfa Laval Separation AB)
The height of the separator is 1.8 m. Sterilizable and contained installation.

Bowl diameters between 528 and 900 mm are manufactured. A medium-sized machine of this type is shown in Figure 11.

3.3. Chamber and Multichamber Bowls

General. A chamber bowl has the shape of a short cylinder with an axial length approximately equal to its diameter. This geometry is used in the most diverse fields, from low-speed versions in mechanical workshops to ultracentrifuges for separation of individual proteins.

Imperforate-Basket Machines. The principle of a simple basket centrifuge is shown in Figure 12. When the basket is full of solids, it must be emptied manually. A high-speed titanium bowl with semi-automatic intermittent solids removal is shown in Figure 13 [18]. After a suitable time, the bowl speed is decreased, and an asymmetrically positioned scraper is engaged and removes the solids. Bottom-fed bowls with similar solids-removal mechanisms are also available. Accelerating vanes are not possible with these mechanisms. Basket-type bowls are also used for liquid – liquid separations, e.g., as centrifugal settlers in countercurrent multistage extraction systems. The mixer often corotates with the bowl on the same spindle.

The Liquid – Liquid Extractor. One of the most widely used multistage extractors can be regarded as a chamber centrifuge with bowl inserts [19]. It is essentially a sieve-plate column wrapped around a shaft. It has a horizontal axis with bearings on both sides of the rotor. It is a hermetic machine in which the feed and the solvent enter the rotor through hollow shafts from opposite sides of the rotor. Feed flows of up to 60 m^3/h can be handled.

Preparative continuous-flow centrifuges can be classified as chamber bowl machines with a completely filled bowl. This is accomplished by the inclusion in the design of mechanical face seals between the rotor and the inlet/outlet. In the bowl is an insert, the core, with wings (septae) that aid in accelerating the liquid. In the wings, channels are drilled for feed and centrate liquids (Fig. 14).

Figure 12. Bowl principle of an imperforate basket machine (vertical section)

Figure 13. Imporforate basket machine with intermittent solids removal (courtesy of CARR Separations, Inc) Vertical section.

The bowls are made of titanium and have volumes of up to 1.7 L; Z is up to 102 000. The inner bowl diameter is up to 190 mm; the sedimentation path is 12 – 59 mm. The machines are used for the sedimentation of large viruses, bacteria, or cell constituents directly to the peripheral bowl wall, or as zonal centrifuges (see Sections 4.2 and 4.3). In the latter machines, the particles of interest are either collected within a density gradient, or on to a cushion of high-density fluid (e.g., sucrose solution) that protects sensitive particles from being destroyed at the bowl wall (see legend to Figure 14) [20]. Especially the machines with the highest g forces must be refrigerated or run under vacuum to avoid heating.

Figure 14. Continuous-flow operation of the CF-32-Ti and JCF-Z (standard pellet core) zonal rotors (from [20], courtesy Oxford University Press)
(A) rotor core and septa. The annular channel (B) forms the common external path to the edge of the rotor (C) and the top of the core (D). Gradient is fed to the wall of the rotor via (B) and (C). Sample passes down the central channel (E), and up over the surface of the core between (F) and (D); the clarified supernatant exits at (G). To unload the rotor an air lock at (H) ensures the passage of dense sucrose to the wall from (B) to (C) and the effluent is collected at (E).

Figure 15. Multichamber bowl (vertical section)

Multichamber Bowl. In this machine, the process liquid flows in the annuli between concentric cylinders (Fig. 15). Having a relatively low separation capability, the machine is used primarily for recovery of valuable solids in dry form and in larger volumes than with the tubular bowl. The maximum bowl diameter is ca. 500 mm, and the solids volume is up to 50 L.

3.4. Tubular Bowl Centrifuges

General. The rotor consists of a long cylinder, into which liquid is pumped (Fig. 16). The tubular bowl geometry is used in low-speed, high-speed, and ultrahigh-speed applications. The high *L*/*D* ratio allows bowl volume and retention time to be increased without sacrificing bowl speed, which can be high if the diameter is kept small.

Figure 16. Tubular-bowl centrifuge (vertical section)

High-Speed Applications. The design shown in Figure 16 is designed for separation of two liquid phases. To remove accumulated heavy solids, the machine must be stopped and dismantled. The length to diameter ratio is usually up to 7 : 1. The small outer diameters make high *Z* values possible (see Table 1). In the high-speed machines, the bowl diameter is up to 130 mm, and the *L*/*D* ratio up to 7. The solids collecting volume is up to 5 L.

Ultrahigh-Speed Applications. For large-volume production the continuous preparative centrifuge shown in Figure 14 has too small a bowl volume. Therefore zonal centrifuges with a large *L*/*D* ratio have been developed. The feed and outlet lines are in principle arranged as in Figure 14. The rotor diameter can be about 130 mm and the rotor volume up to 7 L [5, 21].

Low-Speed Applications. In a design for liquid – liquid separation in multistage extraction plants [22], bowl diameters up to 500 mm are available. The bowl speed is very low, so that *Z* is well below 1000. The mixing of the two phases takes place in the annulus between the rotor and the housing. A similar design has been

used for several years for nuclear reprocessing [23].

Gas Centrifuges. For the enrichment of ^{235}U a number of different techniques have been devised. One is to make UF_6 gas and exploit the density difference between $^{235}UF_6$ and $^{238}UF_6$. A small enrichment is achieved in each separation step, but thousands of units are needed, coupled in series [24]. A modern gas centrifuge may have a diameter of 500 mm and a length of 5000 mm and develop a Z of 147 000 [13]. Development of more efficient rotors is continuing, but details are not in the public domain.

3.5. Decanter Centrifuges

General. The bowl of a decanter centrifuge generally consists of a cylindrical and a conical part. A coaxially mounted internal rotor with helical flights allows for axial transport of the solids by rotation of the conveyor relative to the bowl. The bowl and the conveyor are connected through a gear box which is used to control the relative movement of the conveyor.

Depending on the direction of rotation and whether the conveyor flight is right- or left-handed, the conveyor must rotate faster or slower than the bowl to ensure solids transportation in the correct axial direction. These two designs are known as trailing and leading conveyors, and they result in significantly different flow patterns in the decanter centrifuge (see Section 5.3).

The rotating parts are mounted on a stationary frame, which often carries the drive motor and a back drive system that controls the rotational speed of the sunwheel shaft of the gear box. The frame is connected to the ground through vibration isolators. Decanters are used for liquid – solid and liquid – liquid – solid separation. In the latter case the interface position is given by Equation (10).

The liquid outlet is usually an open outlet with adjustable weir plates, but a stationary paring disk can also be employed. For three-phase operation (liquid – liquid – solid) the choice is between two open outlets or an open outlet combined with a paring disk. In some designs the liquid is picked up in the middle part of the decanter centrifuge through return tubes mounted on the conveyor. In such designs, the inlet is located at the cylindrical end of the conveyor; the liquid and the solids travel cocurrently. In the more popular design with the inlet located near the intersection of the cylindrical and the conical parts of the bowl, the liquid and the solids travel countercurrently.

Horizontal decanters. Horizontal decanters are by far the most common type of decanter centrifuge. The process flow through the decanter is shown in Figure 17. The suspension is pumped through a stationary feed tube into an inlet in the conveyor body where it is accelerated and fed out to a ring-shaped pond of liquid. The liquid flows through the helical channel towards the large end hub, while the solids separate out and settle on the inside of the bowl wall. The clarified liquid leaves the decanter centrifuge over adjustable weir plates, and the relative rotation of the conveyor transports the solids towards the conical end. The solids are conveyed inwards and lifted out of the pond before they leave the centrifuge through openings in the conical part.

The mode of operation is shown in the following video clip.

The conveyor shown in Figure 17 has solid flights which ensure fully helical flow in the pond. Depending on the application the flights often have openings that allow for some axial flow or, in some designs, even entirely axial flow.

In a decanter centrifuge, the radial distance from the center of rotation to the inner liquid surface is large compared to the distance in a disk-bowl centrifuge of the same outer diameter. This is a consequence of the need for space inside of the liquid surface for transporting a large amount of solids without the risk of liquid escaping through the solids discharge ports. The early decanters were mainly conical with a short cylindrical part, if any. The solids handling capacity was high compared to the sedimentation capacity. The main development focus up until the late 1980s was to increase the sedimentation capacity while maintaining solids-handling capacity. The feed suspension for decanters often contains large particles; hence, a disk stack cannot be generally employed. The large radial distance from the center of rotation to the liquid surface further reduces the sedimentation capacity due to high turbulence level. Instead, the sedimentation capacity can be increased by increasing the length of the decanter (see Section 5.3). A more detailed discussion of the sedimentation

Figure 17. Process flow through a decanter centrifuge

performance is given in [25]. A discussion of mechanical and rotor dynamical limitations for long decanters is found in [26]. Since the mid- to late 1980s the dryness or the quality of the solids has governed the development of new decanter designs.

The best quality of the solids usually means the driest solids, but in a few applications, e.g., the thickening of activated sludge, the cake should still be flowable, and the desired solids concentration can be as low as 6 wt %. Such fluidlike solids are difficult to convey by differential movement alone. Since the late 1970s decanters for this application have been equipped with a baffle disk.

Figure 18. Baffle disk designs
Top: Baffle disk; Middle: Baffle plate; Bottom: Conveying baffle.

Figure 18 shows three types of baffle disks: disk, plate, and conveying baffles. The disk and plate baffles have been known since the late 1970s; the conveying baffle was introduced in the mid-1990s.

For rotation of Figure 18 see the following videoclip.

The baffle disk restricts the passage to the solids outlet such that the solids must travel through a relatively small clearance between the outside of the baffle disk and the inside of the bowl wall. The difference in hydrostatic pressure between the liquid and the solids side of the baffle disk transports the solids through the clearance and out of the bowl. When the solids are removed by pressure instead of pure conveyance, the long conical part is no longer needed, and it is often replaced by a short conical part (steep cone, see Fig. 19) with a half-cone angle of 12 – 20°, as opposed to 6 – 12° for other decanters.

The concentration of compressible solids has also greatly influenced the development of decanters. The largest application with compressible solids is the dewatering of municipal sludges.

When solids consist of discrete particles, the dryness can normally be increased by improving the drainage conditions after the solids leave the pond. However, with compressible solids no significant drainage takes place here. Compressible solids are better suited to compaction below the liquid surface. To maximize the load on the solids the decanter must be operated with a thick layer of solids in the cylindrical part. The baffle disks used for thickening are also applicable to dewatering, where they maintain a thick layer

Figure 19. Baffle disk operation with steep cone

of solids in the cylindrical part. With a well-controlled flow of solids across the baffle disk, the volume of solids in the decanter can be further increased to give the maximum retention time without disturbing sedimentation.

The *L*/*D* ratio of the bowl gives a good indication of the relation between solids handling capacity and sedimentation capacity of a decanter. Solids handling capacity depends mainly on the bowl diameter, while the sedimentation capacity depends on both the diameter and the length. For decanters with a trailing conveyor the upper limit for *L*/*D* is around 4.2 at high speed. Lowering the speed or adopting special design solutions has made a few models with *L*/*D* = 5.2 available. For leading conveyor designs the maximum *L*/*D* is generally between 3 and 4.

Horizontal decanters are available in diameters ranging from 150 to 1500 mm, covering flow ranges from 0.3 to 200 m^3/h.

Vertical Decanter Centrifuge. Decanters are also designed with a vertical axis of rotation. This is generally more expensive and offers no immediate advantages over horizontal decanters of the same size. Vertical decanters are often installed in the chemical industry when special requirements are involved:

1) Vaportight or pressuretight casings
2) Operating temperatures above 100 °C or below − 25 °C
3) Very corrosive or toxic operating conditions

Due to the differences in vibration isolators, bearings, and especially seals, the vertical design has advantages under these special conditions. Figure 20 shows the main design differences between horizontal and vertical decanters. Vertical decanters are available in diameters from 180 mm to 750 mm.

Disk Decanter Centrifuge. The newest addition to the decanter family is a vertical decanter equipped with a disk stack [27]. The rationale is to combine the best characteristics of a decanter (dry solids) and of a disk bowl machine (good clarification).

Figure 20. Main design differences between a horizontal and a vertical decanter

3.6. Other Bowl Geometries

A type of field flow sedimentation takes place in the plastic bladder shown in Figure 21. The machine was developed for separation of shear-sensitive mammalian cells, and Z is rather low, about 100 [28]. The bladder is inserted in a rotor, and no seals are needed between the stationary parts and the rotor.

Figure 21. The separation cell of a Sorvall Centritech cell centrifuge (courtesy Sorvall Inc.)

The feed liquid enters at the bottom of the insert and the main liquid outflow is at the opposite end of the bottom of the insert. The heavy liquid phase (cell concentrate) is withdrawn intermittently through the top outlet.

4. Batch Centrifuges

4.1. General

In batch centrifuges a sample of the liquid to be separated is added to the centrifuge container either at standstill or in rotation, and the whole volume remains in the container until the centrifugation period is over. There are two general categories: bucket or bottle centrifuges and batch zonal centrifuges.

4.2. Bottle Centrifuges

Bottle centrifuges are classified as shown in Table 2.

Table 2. Classification of bottle centrifuges (adapted from [21])

	Low-speed	High-speed	Ultracentrifuge
Speed range, 10^3 rpm	2 – 6	18 – 30	35 – 120
Maximum Z	8000	100 000	700 000
Refrigerator	some	yes	yes
Acceleration/Braking	some	variable	variable

The ultracentrifuges can be divided into analytical and preparative ultracentrifuges. The preparative centrifuges, which can belong to all categories in Table 2 are used in research and in the production of biological materials, especially vaccines. The low-speed centrifuge is a valuable analytical tool for characterization of process liquids in the procedures for selecting large-scale centrifuges.

The analytical centrifuge is a sophisticated ultracentrifuge that is used to study optically the sedimentation of small samples (< 1 mL) to determine the molecular mass of macromolecules (→ Plastics, Analysis, Chap. 5.1.3). This method was of major importance in biochemical research, but the emergence of other techniques has restricted its application. More information is given in [1, 5], and [21].

Preparative centrifuge rotors can be classified as swing-out (Fig. 22), fixed-angle (Fig. 23) and vertical (tube axis parallel to the rotor axis). Table 3 summarizes some data for commercially available high-speed and ultracentrifuges [29]. A large number of tubes means a low tube volume, and a large total tube means a lower g force.

Bucket centrifuges can be used for a number of separation methods:

1) Differential centrifugation (pelleting)
2) Density-gradient centrifugation
   (a) rate-zonal (sedimentation velocity) method
   (b) isopycnic (sedimentation equilibrium) method

In pelleting the tubes are filled with a uniform sample. During centrifugation, particles sediment to the bottom of the tube and form a layer or a plug of sediment (see Section 2.1).

Pelleting is too crude a method for many separations of biological materials. Therefore density-gradient separation techniques have been developed in which sedimentation takes place in a medium whose density increases with increasing distance from the center of rotation. This permits separation of several or all components in a sample and also analytical measurements of, for example, sedimentation rate, density, and molecular mass. The sample volumes that can be handled with this technique are, however, an order of magnitude smaller than in pelleting.

Figure 22. Separation in swing-out rotors
The tubes are filled, loaded into each bucket and attached to the central body (yoke) of the rotor; at rest the buckets of the rotor hang vertically (a). As the rotor begins to move the buckets move out so that they are perpendicular to the axis of rotation (b). During centrifugation, the particles sediment down the tube (c). When the rotor comes to a stop (d) the buckets return to a vertical position; there is no reorientation of the liquid in the tubes (from [21], courtesy Oxford University Press)

Table 3. Characteristics of high-speed and ultracentrifuges (adapted from [29])

Rotor type	Number of tubes	Tube volume, mL	Rotor speed, 10^3 rpm	$Z \cdot 10^{-3}$
Fixed angle, small volume	6 – 100	0.2 – 13.5	25 – 120	70 – 700
Fixed angle, medium volume	8 – 12	36 – 50	28 – 70	90 – 500
Fixed angle, large volume	6 – 10	90 – 250	16 – 45	40 – 250
Swing-out, small volume	3 – 6	2 – 5	30 – 65	120 – 500
Swing-out, medium volume	6	13 – 20	28 – 41	120 – 300
Swing-out, large volume	6	20 – 40	25 – 30	90 – 150
Vertical	8 – 12	2 – 39	50 – 100	240 – 645

In the rate-zonal method, the sample is layered on top of the density-gradient liquid. During centrifugation each particle type sediments down the tube according to its sedimentation rate. The density of all sample particles of interest must be larger than the density of the liquid at any specific point in the tube during the whole centrifugation procedure.

In the isopycnic method each particle sediments to the point where its density is equal to that of the fluid.

4.3. Batch Zonal Centrifuges

In density gradient centrifugation in bottle centrifuges, the amount of particles that can be collected is limited by the cross-sectional area of the tube. For larger quantities of sample, zonal rotors of cylindrical or bowl shape have been developed that can handle 50 – 100 times the volume in bottle centrifuges.

5. Fluid Dynamics in Centrifuges

The mathematical equations describing the flow in centrifuge bowls are very complicated, and therefore it is not easy to solve them. The presence of solids complicates matters even more. For mathematical treatments, see [5, 10].

Figure 23. Separation in fixed-angle rotors
The tubes are filled and placed in the rotor pockets (a); tubes for an ultracentrifuge are filled completely and sealed, unsealed tubes must not be overfilled. As the rotor begins to move, the liquid in the tube reorientates during acceleration (b) and the particles sediment down the tube (c). As the rotor comes to a stop (d) the liquid in the tubes reorientates as gravity becomes stronger than the centrifugal force (from [21], courtesy Oxford University Press).

Figure 24. Flow profile between conical discs at high λ values. Particle separation.

5.1. Chamber and Tubular Bowl Centrifuges

The fluid dynamics is complicated even in the simplest of bowl geometries. Sokolov [2] compared actual separation performance with those predicted by a number of velocity distributions. He found that the best fit was obtained with a plug-flow model, but the separation was overestimated. The phenomena that make the simplified flow models inaccurate are end effects, vortices between the wings of a wing insert, velocity lag, and nonideal feed accelerators.

5.2. Disk-Bowl Centrifuges

The disks in the bowl split the flow into thin layers. Usually the flow between the disks is laminar, which facilitates particle settling. The critical Reynolds number for transition to turbulent flow increases with decreasing disk spacing and increasing bowl speed. This is also beneficial since a short disk spacing makes the settling distance short, and the high bowl speed increases the settling velocity. Figure 24 illustrates the situation. The liquid is driven towards the center by a pressure gradient. The particle, in this case denser than the liquid, is considered to be separated if it reaches the underside of the upper disk. The particle movement is influenced by centrifugal force and by the liquid drag. The flow pat-

tern of the liquid is determined by the interplay of inertial, friction, and Coriolis forces. The flow profile is determined by a dimensionless number λ, defined as

$$\lambda = t \cdot \sqrt{\frac{\omega \sin \alpha}{u}} \tag{18}$$

When λ is small the velocity distribution is parabolic, but for values > 5, normally encountered in industrial centrifuges, the velocity profile breaks up in two so-called Ekman layers, in which the net transport of liquid towards the center takes place. Since separated particles (heavy phase) are collected at the underside of the disk, they are subjected to a strong shear force from the Ekman layer that drags the particle towards the liquid outlet. The velocity in these layers increases with increasing λ, that is, with increasing bowl speed. Therefore a higher bowl speed cannot always be fully utilized because of the counteracting shear force.

Figure 25. Comparison of calculated (a) and actual flow patterns (b) in a disk bowl [30]

In between the Ekman layers is the geostrophic layer. In Figure 25 its streamlines have been made visible by dye injection in the geostrophic layer and can be compared with the calculated streamlines in the gap between two discs with radial spacers and a distribution hole through which the liquid enters [30]. Particle separation has also been studied in the same geometry [31]. It has been found that the drag force on the particles collected at the underside of the disk depends on the position on the disk, and that some particles are easily separated, whereas others are forced towards the center. The drag force can be computed [32] and the calculations of separation efficiency including the drag force verify these findings.

Many bowls have an open chamber in the center in which the nonrotating feed liquid is received. In many cases the turbulence in the feed zone breaks up shear-sensitive particles, making separation more difficult. For many applications it is therefore advantageous to use a machine with feed from below. In other applications a special inlet geometry (e.g., a disk inlet) dissipates the energy over a larger volume and decreases the shear forces [33]. It can also reduce air entrainment and foaming.

5.3. Decanter Centrifuges

The liquid flow patterns in a decanter centrifuge have been studied by using a transparent bowl operating at reduced speed. One area of particular interest is the difference between trailing and leading conveyor design. Operation of full-scale decanters of the two types have often revealed some unexplained differences. Figure 26 shows photographs of the flow patterns in the transparent bowl for the two design types. In both cases the decanter operates with a constant feed flow of water, and the inlet position is close to the intersection between the cylindrical and the conical part. At $t = 0$, a pulse of blue color is added to the feed stream and the position of the colored liquid is photographed after 5, 15, 30, and 60 s. The findings can be summarized as follows:

In the *trailing conveyor,* the feed travels rapidly away from the feed position in a thin surface layer in the direction of the liquid outlet. As the liquid flows along the helical path the friction against the flights gradually changes the velocity profile into an increasingly accelerated stream. As the acceleration increases, the depth of the surface layer also increases, and the velocity towards the outlet drops significantly.

Figure 26. Flow patterns in decanter centrifuges
A pulse of blue color is added to the constant flow of water at $t = 0$. Photos are taken at 5, 15, 30, and 60 s with stroboscopic light from behind. With the trailing conveyor design the flow starts as a thin surface layer flow at the feeding position. As the liquid travels towards the outlet, the flow profile develops into a less turbulent profile that is better suited for sedimentation. A substantial part of the liquid is recirculated back for remixing at the inlet. In the leading conveyor design the liquid travels in the wrong direction at the surface at the entrance in the pond. After being brought up to full rotational speed, it moves in the right direction in a layer below the surface and flows almost as a plug flow in the cylindrical part.

The existence of a surface layer is well known from the literature, but in many cases depth of the layer is assumed to be constant. This leads to a poor description of the sedimentation capacity of long decanters as it is the change in velocity profile that ensures constantly improved sedimentation conditions with increasing distance from the inlet. The variation in velocity profile also includes a return flow, in which a significant amount of liquid flows back to the inlet, where it re-entrains the incoming feed stream. The return flow to some extent protects the solids on the bowl wall from being dragged along in direction of the main flow. (No solids are present in the test shown in Figure 26.) Due to the improved sedimentation capacity of long decanters, the L/D is often chosen to be as high as possible for this design type. The limiting factors are the solids handling capacity and rotor-dynamics considerations.

In the *leading conveyor,* the surface layer starts out in the wrong direction. It has to come back again in a subsurface layer and, after passing the inlet position, where some of it is re-entrained, it flows almost like a plug flow with constant velocity towards the liquid outlet. The plug flow velocity profile is ideal for sedimentation, and this design type has quite a good sedimentation capacity even for short machines (low L/D). The limitation of this design is that the

full feed stream must pass the inlet twice, which reduces the space available for the transport of solids. Furthermore the direction of the solids is opposite to the returning feed flow, and this limits the amount of solids that can be transported past the critical area. As a result decanters with a leading conveyor have smaller values of *L*/*D*.

The *presence of solids* will, of course, also influence the flow patterns, especially when they take up the majority of the pond volume, and this further complicates the fluid dynamics of the decanter centrifuge. Such conditions cannot be studied in the transparent decanter shown in Figure 26, but full-scale tests with low solids load confirm the general impression from the observed flow patterns [25]. As the flow pattern inside the decanter depends on the design type (leading or trailing conveyor) and on *L*/*D*, one has to be very careful when scaling from one decanter to another. Generally it is recommended only to scale between the same design type and similar *L*/*D* values unless the scaling is supported by experience with the particular application.

6. Centrifuge Technology

6.1. Rotor Dynamics

All rotating bodies vibrate at certain speeds. At these critical speeds the rotational frequency of the assembly is equal to one of its natural frequencies. The operating speed must therefore be selected so that it differs from these frequencies and their harmonics. At a critical speed any unbalance load will cause heavy vibrations and high stress to the bearings and the supporting system. If the rotor at a critical speed hits nonrotating parts of the assembly the deflections will suddenly be even greater and may lead to even more serious damage. Modern centrifuges are therefore designed with sufficient clearances between rotating and nonrotating parts that contacts are very unlikely.

Centrifuge rotors are of two kinds: those operating with fixed bearings at subcritical speed and those mounted with flexibly mounted bearings for operation at supercritical speed. The latter category includes disk-bowl (Figs. 2 – 11), multichamber-bowl (Fig. 15) and high-speed tubular-bowl (Fig. 16) machines. Lately, decanters with supercritical operation have been built [26]. Otherwise, all decanters are designed for subcritical operation.

In the supercritical machines, the deflections experienced when passing the critical speeds at starting and stopping can be dampened by mounting the bearings on springs or rubber elements.

6.2. Materials Selection

Bowls. In selecting a material for a centrifuge bowl, a number of conflicting demands have to be met. The material must have high yield stress, high tolerance to fatigue, high corrosion resistance, and low cost.

Although exceptions exist, the centrifuge designer strives for the highest possible *g* number combined with a bowl volume large enough to provide an optimal residence time or solids space. For steels in general, the higher the corrosion resistance is, the lower is the strength. The tendency today is to increase yield stress in materials with the required corrosion resistance, because this is in many cases the cheapest way to improve the cost/performance ratio.

In disk-bowl and decanter centrifuges, Duplex steels are very common [34]. In applications with moderate corrosiveness, a DIN 1.4462 steel (in USA S31803, in Sweden 2377) is often used. Its yield strength $R_{p0.2}$ is 450 MPa. Other Duplex steels are under development [35]. For applications of low corrosiveness and low chloride ion content, DIN 1.4418 steel (in Sweden 2387) with $R_{p0.2}$ = 750 MPa is often employed. Unalloyed steels are used in some decanters and low-cost basket centrifuges. Hastelloy is used for extreme conditions in the chemical industry; the yield strength is low compared to the other materials mentioned above. For special purposes, aluminum alloys can also be used. Alloyed titanium (typical $R_{p0.2}$ = 830 MPa) is the bowl material in batch and continuous-flow zonal centrifuges and, together with aluminum, in medium- and high-speed bucket centrifuges. The bowl of the basket machine in Figure 13 is made of titanium for use in the biotechnology and fine-chemicals industries.

The stresses in the bowl material are the result of the weight of the material itself and the bowl contents. The self-stress accounts for 50 – 65 %

of the tangential stress; the remainder is due to the weight of the bowl contents (density 1000 – 1500 kg/m^3). It can be shown [13] that the maximum possible peripheral speed $\omega_{\max} r_{\text{outer}}$ is approximately proportional to the square root of the yield strength. Therefore $(\omega_{\max} r_{\text{outer}})^2 = Z_{\max} r_{\text{outer}} = \text{const.}$, and $Z_{\max}$ is approximately inversely proportional to the outer bowl radius. This is valid for geometrically similar machines.

The maximum peripheral speed of a solids-ejecting bowl (Fig. 4) made of DIN 1.4462 steel is about 170 m/s. For other geometries with this material (e.g., Figs. 2 and 10) it is somewhat higher. Zonal rotors made of titanium have maximum peripheral speeds of the order of 300 m/s. Gas centrifuges can run even faster, partly on account of a lower density of the bowl contents; a peripheral speed of 600 m/s has been reported [13].

The axial stresses on the bowl are one order of magnitude smaller than the tangential stresses.

The fatigue tolerance of the material must be taken into account in design. Modern solids-ejecting bowls are designed such that no restrictions on number of discharges need to be imposed. Some zonal centrifuges record each cycle of use because the bowl lifetime is determined by fatigue.

Bowl parts subject to less stress are made from stainless steels (DIN 1.4401 or 1.4404; U.S. equivalents 316 and 316L), from mild steel or, in the absence of alkaline or other corrosive liquids, bronze. Disks for some small disk-bowl machines are made of plastics.

Frames. Most frames of industrial machines are made of cast iron. They are equipped with vibration-dampening rubber feet, which are bolted to the floor.

Covers. The material for the covers of industrial high-speed machines is most often stainless steel (DIN 1.4401 or 1.4404; U.S. equivalents 316 and 316L). Also carbon steel, plastics, and, in the absence of alkaline liquids, silumin are commonly used.

Solids Receptacles. In nonfood and mildly corrosive applications, painted cast iron is used. For food and corrosive applications stainless steel is common. When the solids are erosive, replaceable solids deflectors with hard surfacing or polyurethane linings are mounted.

Nozzles. In nozzle machines the discharged solids are often erosive. Therefore the nozzles have inserts of tungsten carbide, sometimes sapphire. For nonerosive solids, stainless steels are used.

Elastomers and Plastics. Nitrile, butyl, EPDM, polyurethane and fluoro rubber are used in O-rings and gaskets. For food applications, FDA and BGA approved materials may be specified. A large number of plastics materials are used. Polyamide, PTFE, and polyether ether ketone are some examples for large industrial machines. Polycarbonate and polysulfone are often used for the tubes and bottles in bucket centrifuges.

7. Centrifuge Selection

7.1. Introduction

The choice of type and size of centrifuge is a combined theoretical and practical exercise. In most cases the final choice for a new centrifuge application cannot be made without testing the type of centrifuge preliminary selected at between 25 and 100 % of the final plant flow rate. The reasons for this are at least two. One is the elimination of the technical risk. The other is so far most common in the industry producing pharmaceuticals. In pre-approval inspection, the inspecting and licensing authorities are concerned with the comparability between batches of product from the development phase and from the production phase. Since the validation procedures are costly and time-consuming, it is very important to already select at least the right type of centrifuge at pilot scale.

A combination of different types of centrifuge in series is often the most cost-effective solution for a given problem. Also a filter in series can be a valuable complement to a centrifuge.

Alternative process and plant designs should be discussed before the centrifuge type and size are finally selected.

7.2. Main Process Parameters [40]

The *feed flow rate* is often determined by the available or required time to process one batch.

The *separability* can be estimated on a bench scale by test tube centrifugation (spin test, see Section 7.3). The *flow of solids* is the feed flow rate multiplied by the percentage by volume of suspended solids. It is this solids flow rather than the suspended solids content alone that influences the choice of machine type. Different machine types differ in their ability to produce high *concentrations of separated solids* (see Table 1). The *required degree of separation* has a strong influence on the possible flow rate in a given machine. The wider the particle size distribution, the more the flow rate must be reduced to increase the degree of separation degree from, e.g., 90 to 99 %. *Solids rheology*, i.e., the reaction of the solids to pressure and shear forces, is very important for the choice of machine type. Pseudoplastic, i.e., shear-thinning, solids will flow out of the machine type shown in Fig. 10 at high solids contents. Shear-thinning solids may have an angle of repose of close to 0° (see Section 3.2). Dilatant solids can only be discharged in concentrated form without manual handling from peripheral-nozzle machines (Fig. 8) and decanters (Fig. 17). Because of the content of a valuable dissolved substance in the entrained liquid, *washing of solids* may be necessary. Another reason for washing solids is to remove impurities. This is usually done by resuspension and further separation steps.

7.3. Test Tube Centrifugation (Spin Test)

The most important task for a spin test is the *determination of separability*, i.e., the settling velocity. In practice, it is difficult to calculate, since often the information needed for the Stokes Equation is incomplete. The spin test is done by spinning a sample of the feed stream for different periods of time and/or at different g numbers. For each spin the supernatant is analyzed with regard to the process parameter of interest, e.g., residual solids content, turbidity, cell count, or content of heavy liquid. Thereafter the spin time that gives acceptable supernatant quality is recorded, and a preliminary Σ value is calculated from Equation (19).

The swing-out test tube (bottle) centrifuge is shown schematically in Figure 1. The shaded volume with height h is the volume taken for sampling. Combining Equations (9) and (13) and rearranging gives a preliminary value of $Q_{\mathrm{theor}}/\Sigma$:

$$\frac{Q_{\mathrm{theor}}}{\Sigma} = \frac{g \ln \frac{r_2}{r_1}}{T\,\omega^2} = u_{\mathrm{g}} \tag{19}$$

For a test-tube centrifuge with an angle head, $\ln(r_2/r_1)$ is exchanged for $\ln(1 + D/r_1 \cos\beta)$, where D is the inside diameter of the tube, and β is the angle between the tube and the axis of rotation.

The spin test is also a valuable tool for measuring *phase volume ratios*. The volumetric solids content, as determined by the spin test is an important parameter in determining a crude mass balance around the centrifuge. Spin tests performed under different time and g number conditions also give an indication of solids compressibility and rheology. It is also valuable to work up a sample of the solids phase after spinning to give an indication of its dry solids content after centrifugation. A spin test makes it possible to identify the nature and amount of different types of solid impurities, which may be harmful to the performance of the chosen machine.

7.4. Important Properties of the Process Streams

Particle size and *density difference* are the most important data, and in applications for sedimenting centrifuges they vary within wide limits: the particle size between 0.2 µm and 0.5 mm and the density differences between 15 and 2000 kg/m^3. The latter figure is valid for solid particles. The density differences between liquid phases are seldom larger than 300 kg/m^3. Often particle properties are unknown and/or difficult to measure. The spin test as described above often serves as a good measure.

As many as possible of the following data should be determined before the selection of a centrifuge is made [40]:

- Chemical composition of liquid and solid phases
- Densities of liquid and solid phases
- Viscosities of liquid and solid phases
- Particle size distribution
- pH
- Temperature
- Vapor pressure

– Shear sensitivity
– Angle of repose
– Toxicity
– Explosion hazard

Apart from Stokes Law the *density* is important for the stress in the bowl material. *Low pH* and *high temperature* may, together with even a moderate chloride concentration, lead to difficulties with *corrosion*. The corrosive properties of process materials can be very serious but it is in many cases possible to reduce the corrosion rate by intermittent washing with caustic solution, e.g., after every 4 – 5 h of operation to re-establish a passivating layer on the metal surfaces. *Erosion* may be a problem with many inorganic crystalline materials, including silt-containing process water. This may necessitate the use of hydrocyclones to remove these particles. The *angle of repose* (see Section 3.2) is the angle a cone of solids forms if allowed to settle,

Table 7. Some fuel and energy-generation applications of centrifuges

e.g., between the nozzles in a nozzle bowl. If it is 0° or close to 0°, the flow properties are extremely good. The most shear sensitive cells are mammalian cells. In the Centritech machines the *g* number is limited to 100, more than one order of magnitude lower than for other centrifuges. Some protein precipitates are also sensitive to shear [41], including those formed in the maturation tanks in breweries. Many bacteria are sensitive, but yeast cells are robust.

7.5. Improvement of Separability

According to Stokes' law the settling velocity improves when the density difference and the particle density increase and when the viscosity decreases. Ref. [42] lists physical, chemical and biological techniques for conditioning of fermentation broths. The most widely used are coagulation and flocculation, but also aging, pH change, and addition of enzymes or other chemicals are employed.

7.6. Pilot Machine Testing

After maximizing the separability of the feed stream, the preliminary $Q_{\mathrm{theor}}/\Sigma$ is determined by spin tests. The machine type and size are tentatively chosen on the basis of the preliminary mass balance and on the required Q_{act}. With the separation efficiency μ, taken from Section 2.2, Q_{act}/Σ can be calculated from the equation

$$\frac{Q_{\mathrm{act}}}{\Sigma} = \mu \cdot u_{\mathrm{g}} \tag{20}$$

It is often advisable to make a test with the chosen type of machine. The purpose of such a test is to obtain a more reliable Q_{act}/Σ value, but also to assess solids flow properties, emulsification and particle break-up tendencies and clogging risks. Recommended test procedures for a number of centrifuge types are described in [43].

7.7. Scale-Up

For all types of centrifugal separators, the Q_{act}/Σ value can be used for scale-up of the sedimentation performance if some general considerations are taken into account:

- The type of centrifuge is similar.
- The geometry is similar. For decanters, e.g., feed inlet position, *L*/*D* ratio, or beach angle. For disk machines, e.g., disk spacing, cone angle, and number of feed holes.
- The bowl speed gives similar linear velocity of wings etc. when treating shear-sensitive process feeds.
- The λ value (Eq. 5) is almost the same in both machines.

– The larger machine has no hydraulic limitations with respect to the calculated flows. Potential limitations are inlet and outlet pressure drops, paring-disk pumping capacities (upper and lower limits), and the upper and lower limits of solids flow.
– No mechanical limitations, e.g., power transmission, and, in decanters, gear-box torque. The equation for scaleup is

$$\left(\frac{Q_{\text{act}}}{\Sigma}\right)_1 = \left(\frac{Q_{\text{act}}}{\Sigma}\right)_2 \; (= \mu\, u_{\text{g}}) \tag{21}$$

where indices 1 and 2 denote the two machines. Direct calculations of u_g and μ are thus avoided, as are hindered settling effects.

8. Applications

Sedimenting centrifuges are used in the most diverse fields. Tables 4–12 list the most important applications in various industries.

Hydraulic oil purification	x	x		
Paint waste			x	x

The most important applications of the commonest centrifuge type, the radial solids-ejecting centrifuge, are production of milk and other beverages (Table 8) and purification of fuel and lube oil on board ships (Table 10). The decanter centrifuge is the most widely used piece of equipment for municipal sludge dewatering, its largest application. Another major decanter application in terms of number of units is vegetable oil production (Table 9), but other food areas are also important (Table 8).

Since sedimenting centrifuges are very suitable for rapid liquid – liquid separation it is not surprising that oil – water separation is the most successful area, either because of instability of products (food) or small space requirements (on board ships). Large decanters are very much in use in polymer production (Table 4). Disk-bowl and decanter centrifuges are used in the chemical industry for hundreds of small volume chemical products, which are too numerous to list here.

Large peripheral-nozzle machines are used in production of starch from various raw materials (Table 8).

A general area of use is lube oil and hydraulic oil purification.

In general, centrifuges that require manual cleaning and removal of solids (solid-bowl disk, tubular, chamber, and multichamber bowls) are becoming obsolete, except in those cases where the solids are very valuable, e.g., in the pharmaceuticals or fine-chemicals industries; where the solids content in the feed material is very low; or where cheap manual labor is available. In the latter case the simple imperforate basket centrifuge is used in the most diverse fields. Sophisticated equipment, such as chamber-bowl machines with intermittent solids removal, are becoming more and more interesting. More exotic bowl materials, (e.g., titanium) are spreading also to large centrifuges, increasing the range of applications. The hydrodynamics of decanter centrifuges in particular are becoming better understood, and this will in time lead to new applications. One trend is that centrifuges are becoming larger, but low-cost centrifuges made of lightweight materials are taking over some classical filter applications, e.g., purification of hydraulic oils.

1. Introduction

Compared to the common process design of reaction and separation in series, the integration of both process steps into one unit operation may improve the reaction yield and the separation efficiency. Besides reactive distillation (→ Reactive Distillation), reactive extraction, and reactive absorption, coupling of chemical and biochemical reactions with chromatographic separation is an especially attractive integrated process for producing high-purity products. The chromatographic reactor can be defined as "a chromatographic column in which a solute or several solutes are intentionally converted, partially or totally, to products during their residence in the column". As the apparatus is employed as reactor and separator, both conversion of the starting material and separation of the components take place in the column [1]. A more general definition is to define a chromatographic reactor as unit operation in which a chemical or biochemical reaction is combined with a chromatographic separation.

In chromatographic systems, a fluid mobile phase is in constant contact with the stationary phase during its passage along the column. The mobile phase may be a gas or a liquid, and therefore a distinction between gas chromatographic reactors (GCR) and liquid chromatographic reactors (LCR) can be made. The most common stationary phase in chromatographic reactors is a solid adsorbent, in the form of particles with large internal and external specific surface areas. The stationary phase may also be a liquid coating on a solid support, or chemical substances of varying chain length and molecular mass bonded to the surface of a support. The reaction can take place in the stationary phase and/or in the mobile phase. Heterogeneous reactions can be catalyzed by the adsorbent itself or by an additional catalyst that is mixed with the adsorbent.

Chromatographic reactors are used for analytical and preparative applications. On the analytical scale, they are used for determining reaction kinetics, characterizing the stationary phase, or examing the interaction between mobile and stationary phases. On the preparative

10.1002/14356007.c07_c01

scale, chromatographic reactors are employed for the production of chemicals and the preparation of unstable reagents for laboratory use. The use of chromatographic reactors on a preparative scale is especially attractive where a chromatographic separation has already been used for purification of the products. Laborious screening of a suitable adsorbent can then be omitted, and only the catalyst needs to be chosen. Hence, the cost of process development is significantly reduced.

The integration of reaction and chromatographic separation offers various advantages. For reversible reactions, conversion can be increased beyond chemical equilibrium by continuously removing the products from the reaction zone. Combination of two unit operations in one apparatus leads to smaller capital expenditure. In analytical applications, impurities in the reactants can be easily detected, and therefore the expense of prior preparation of the components can be reduced. The analysis of the measurements is more comfortable because no additional instrument is needed for determining the amount of the reactants and the products.

Although chromatographic reactors offer various advantages, no commercial application on a preparative scale is known so far. Nevertheless, especially in the field of enzymatic reactions, the possibility of applying a chromatographic reactor is increasingly being examined. Therefore, this new process is expected to find its first industrial applications in biochemical reactions.

2. Types of Chromatographic Reactors

Most chromatographic reactors are identical to the analogous apparatus used exclusively for separation. The only reactors that have especially been developed for the combination of reaction and separation are the Hashimoto reactor and the reversed flow reactor.

Batch Chromatographic Reactor (BCR). The simplest way to realize a chromatographic reactor is to run it in a batch mode. Figure 1 illustrates the operating principle of a batch chromatographic reactor for a reversible decomposition reaction. The starting material A is injected as a sharp pulse into the column. During its propagation along the column it is converted to the products B and C. The different adsorption of components B and C leads to different propagation velocities, and the products are separated from each other. Therefore, it is possible to totally convert the starting material into the products although the reaction is limited by chemical equilibrium. Additionally, no separation unit following the chromatographic reactor is necessary to obtain the products in high purity. The operating conditions should be chosen so to achieve complete conversion. Otherwise, an additional separation unit is necessary to recycle the starting material.

Figure 1. Schematic representation of the chromatographic batch reactor

Two fields of application have been described in the literature so far. First, the BCR can be used to analytically determine the reaction rate constants or the mechanism of a reaction and to characterize the stationary phase (see Chap. 7). The BCR can also be used for the production of chemicals (see Chap. 6).

After the invention of the chromatographic reactor in 1961 [2], [3], most experimental and theoretical studies dealt with the concept described above. Research on preparative-scale chromatographic reactors has mainly focused on continuous chromatographic reactors.

Continuous Rotating Annular Chromatograph (CRAC). By using a cylindrical annulus, the chromatographic reactor can be operated continuously. The annulus space is formed by employing two concentric cylinders. The annulus, packed with adsorbent and/or catalyst, is rotated continuously. The components are fed into the apparatus through a fixed port at the top of the annulus. Additionally, eluent is uniformly introduced over the whole cross section at the top of the apparatus. A component in the mobile phase moves in an axial direction (because

of gravity and pressure difference) and in a tangential direction (because of the rotation of the apparatus). An adsorbed molecule only moves tangentially. Because of the different adsorption of the components, their residence time in the stationary phase differs. Therefore, the components can be collected at fixed outlet ports at the bottom of the annulus (Fig. 2).

Figure 2. Schematic representation of the rotating cylindrical annulus

This principle was first introduced by MARTIN [4]. The possibility of applying this concept to chromatographic reactors was demonstrated by CARR et al. for the hydrolysis of methyl formate [5]. Other reactions that have been performed with the rotating cylindrical annulus are the enzyme-catalyzed inversion of sucrose [6] and the saccharification of starch to maltose [7].

The production rate of the rotating cylindrical annulus is comparable to that of the BCR [8]. The rotating annulus can be considered as a number of batch columns arranged in a circle and periodically charged with feed. This also explains why the performance of the two variants is the same.

A major drawback of the BCR and the CRAC is the large amount of eluent needed to operate the process. This also leads to a high dilution of the products. Another disadvantage is the poor use of the adsorbent. These drawbacks led to the development of continuous countercurrent processes.

True Moving Bed Chromatographic Reactor (TMBCR). In the true moving bed chromatographic reactor (TMBCR), also called countercurrent moving bed chromatographic reactor, the solid phase is moved in the opposite direction to the liquid flow. The main advantage of such an arrangement is the countercurrent flow, as in heat exchangers or distillation columns, that maximizes the average driving force. Thus, the efficiency with which the stationary phase is used increases. The countercurrent moving bed reactor was first mentioned by TAKEUCHI et al. [9]. On the basis of theoretical studies on a reaction of type $A \rightleftharpoons B$ an improvement in the conversion compared to equilibrium was found. For consecutive reactions of type $A \rightarrow B \rightarrow C$, the selectivity for the intermediate product in consecutive reactions can also be improved. An experimental study of the hydrogenation of 1,3,5-trimethylbenzene to 1,3,5-trimethylcyclohexane in excess H_2 confirmed the results found for reversible reactions of type $A \rightleftharpoons B$ [10].

The movement of the solid particles is difficult to realize. One reason is the unavoidable backmixing of the solid that reduces the efficiency of the process. Another problem is the abrasion of the particles caused by the movement.

Simulated Moving Bed Chromatographic Reactor (SMBCR). The invention of the simulated moving bed (SMB) concept [11] overcame the difficulties related to the movement of the solid. The valves of interconnected columns are sequentially switched in the direction of the fluid flow. This means the inlets (desorbent, feed) and outlets (extract, raffinate) are regularly changed. The time between the switching of the valves is called a cycle. At the end of the cycle, each inlet and outlet is moved one step in the direction of fluid (Fig. 3 A). Therefore, the countercurrent movement of the phases is simulated by sequentially changing the in- and outlets. When the number of columns tends to infinity and the switching time and column length tend towards zero, the performance of an SMB unit becomes identical to that of the corresponding TMB process. The principle of an SMB chromatographic reactor can be explained by considering a reversible reaction of type $A \rightleftharpoons B + C$ in an SMB apparatus consisting of four sections. The in- and outlets can be used to define four sections. Each section accomplishes a special task that is realized by the right choice of flow rates (Fig. 3 B):

1) *Section I* is located between the desorbent and the extract nodes. The flow rate is higher

Figure 3. Schematic representation of the SMBCR
A) Configuration of the apparatus in two consecutive cycles; B) Axial profiles of the components at the end of a cycle (steady state)

than in all the other sections. This high flow rate is necessary to remove the more strongly adsorbed product (component B) from the adsorbent.

2) In *section II*, between the extract and the feed nodes, components B and C are formed. The less strongly adsorbed product (component C) is desorbed, whereas B is still held on the adsorbent. The extract stream therefore contains the more strongly adsorbed product.
3) *Section III* is also needed for the decomposition of component A. Here component B is adsorbed. Thus the fluid collected at the raffinate port has a high concentration of component C.
4) Before the fluid is recycled, it is cleaned in *section IV*. Component C is adsorbed and recycled to section III with the adsorbent.

Besides the concept described above, the SMBCR can be varied in different ways. For example, it can be run as open SMBCR, i.e., without a recycle stream [12], [13]. In this case, sometimes section IV is omitted, and the raffinate is collected at the outlet of section III.

Another variant has been developed for gas – solid reactions. Again, the solid flow is simulated by switching the valves. For the hydrogenation of 1,3,5-trimethylbenzene, a reactor consisting of three sections is employed. A mixture of adsorbent and catalyst is packed in the

column. The feed is injected in the feed section and reacts to form the product 1,3,5-trimethylcyclohexane, which is less strongly adsorbed than the starting material. The product stream is totally removed at the outlet of the feed section. The feed has to be switched to the next column in line before the starting material 1,3,5-trimethylbenzene reaches the outlet of the feed section. In the next cycle the former feed column, which now belongs to the carrier section, contains the starting material and the product. In the carrier section both components are desorbed and fed into the feed section. But it is not possible to totally remove the less strongly adsorbed starting material in this section. This is why a third section, known as the extra carrier section, is needed to obtain a high product purity. In this section the more strongly adsorbed starting material, that remained in the column, is removed by an extra carrier stream. At the end of the cycle this column should no longer contain either component. Therefore, after switching the valves, e.g., this section becomes the feed section, 1,3,5-trimethylcyclohexane can be collected at high purity (Fig. 4 A).

In the apparatus developed for the oxidative coupling of methane two modifications to that shown in Figure 4 A must be made. First, in each section two separation columns are in series to a reaction column. Splitting the reaction and separation is necessary because of the high temperature required for reaction, whereas adsorption has to be operated at lower temperatures [14]. The second modification is necessary because of the reversed reactant and product elution order. Accordingly, the starting material reaches the column outlet first. The feed is injected in the feed section and reacts to form the products ethylene and water. The feed has to be switched to the next column in line before the starting material reaches the outlet of the feed section. In the next cycle the former feed column, which now belongs to the carrier section, contains the starting material and the products. Because of the different propagation velocities, the starting material and the products are separated in the carrier section. At the end of the cycle the first separation column only contains ethylene and water. After the switching of the valves the products can be removed by an extra carrier stream (Fig. 4 B). Further details concerning the oxidative coupling of methane and the hydrogenation of 1,3,5-trimethylbenzene can also be found in Section 6.1.

Continuous Reactor for Producing High-Fructose Syrup (CRHFS). This reactor concept was developed to achieve high conversion in the case of reactions of type $A \rightleftharpoons B$, e.g., the isomerization of glucose (see Section 6.2). This can be achieved by using different columns containing the adsorbent and the catalyst. The reactor is also operated according to the concept of simulated moving bed chromatography but consists only of three sections (Fig. 5). In section III, reaction and adsorption columns alternate, whereas sections I and II consist only of adsorption columns. The switching of the in- and outlets of the adsorption columns is similar to the SMBCR, but the position of the reaction columns does not change. These columns are connected to the adsorption columns in section III and do not move into another section. In section II the starting material is separated from the product and carried back to the reactors in section III [15].

Reversed-Flow Reactor (RFR). The concept of the chromatographic reactor with reversed flow is similar to the catalytic heat regenerator reactor. In the last named, the heat capacity of the catalyst is used to act as a thermal buffer. Therefore, the feed gas can be heated. In the chromatographic reactor not heat but mass, i.e., one reactant, is stored by adsorption (Fig. 6). The principle of the reactor can be explained by considering a reaction of type $A + B \rightarrow C$. Component B is adsorbed whereas components A and C are not adsorbed on the catalyst. The adsorbable reactant is continuously fed into the reactor via a sidestream and is adsorbed on the stationary phase. Component A is introduced at one end of the reactor and reacts with the adsorbed reactant to form product C. Before component B reaches the outlet, the flow is reversed, so that reactant A is introduced on the other side of the reactor and the concentration wave of component B propagates in the other direction.

Advantages of this reactor are the total conversion of the reactants, its insensitivity to fluctuation of the input conditions (flow rate, concentration), and simpler control of the reactor.

Figure 4. Schematic representation of the multi column SMBCR used by CARR et al.
A) Hydrogenation of 1,3,5-trimethylbenzene; B) Oxidative coupling of methane

A practical application of this concept has been found in the selective catalytic reduction of nitrogen oxides in stack gas with ammonia:

$$4\,NO + 4\,NH_3 + O_2 \longrightarrow 4\,N_2 + 6\,H_2O$$

Ammonia is selectively adsorbed on a stationary phase which also acts as a catalyst. By periodically reversing the flow, high conversion of NO (>99 %) and small NH_3 slip values (<1 mL/m^3) can be obtained. A list of conditions that should be fulfilled for the operation of a reversed flow reactor for the selective reduction of nitrogen oxides using ammonia has been given by AGAR and RUPPEL [16]:

- The adsorption must be selective and strong enough to yield reasonable cycle times.
- The rate of adsorption must be comparable to the rate of the reaction.
- The rate of the desorption must be slow.
- The reaction must be irreversible and free of side reactions.

3. Modeling of Chromatographic Reactors

Different models to describe chromatographic reactors have been published. They can be classified according to the modeling approach and the effects that are taken into account (Fig. 7). A chromatographic column can be described in two different ways. In the first approach the column is divided into theoretical plates that are connected in series. The second approach is based on the differential mass balance. An SMB process can also be described in two different ways. It can be approximated to be an equivalent true moving bed reactor or described as different fixed columns connected to each other, whereby the in- and outlets are periodically shifted.

Models of different complexity can be built. A distinction is made between models that take mass transfer resistance into account and models in which equilibrium between the solid and the fluid phase is assumed. By employing the model of axial dispersion the axial mixing along the column can be described. In chromatography two main mechanisms contribute to axial dispersion: molecular diffusion and eddy diffusion. These can be lumped together using a single axial dispersion coefficient. Other parameters that can be used to develop a more detailed model are intraparticle diffusion and the adsorption – desorption kinetics. The adsorption on the stationary phase can be described by an adsorption isotherm, which can have a linear or nonlinear relationship. Depending on the catalyst used, the reaction can either take place in the fluid phase or in the stationary phase.

3.1. Adsorption Isotherm and Reaction Kinetics

Various approaches for modeling the relationship between the equilibrium concentration of

Figure 7. Modeling of chromatographic reactors

a component in the stationary and the mobile phases can be found in the literature [17].

For small concentrations, this relationship can be sufficiently described by a linear isotherm:

$$q_i = K_{\mathrm{H},i}\, c_{\mathrm{p},i} \tag{1}$$

where q_i is the concentration of component i in the stationary phase, $K_{\mathrm{H},i}$ is the Henry coefficient and $c_{\mathrm{p},i}$ is the mobile-phase concentration in equilibrium with the solid-phase concentration.

Nonlinear adsorption can be described by the competitive Langmuir isotherm model:

$$q_i = \frac{K_{\mathrm{H},i}\, c_{\mathrm{p},i}}{1 + \sum\limits_{j=1}^{n} b_j\, c_{\mathrm{p},j}} \tag{2}$$

where n is the number of components in the system and b_j is the ratio of the rate constants of adsorption and desorption.

For modeling the reaction kinetics, the reaction rate is given as a function of the concentrations of the starting material and, for a reversible reaction, of the products. For the formulation of the rate equations for chemical reactions, see → Principles of Chemical Reaction Engineering and [18].

3.2. Modeling the BCR

The Model of an Ideal Chromatographic Reactor. The model of an ideal chromatographic reactor can be used to examine the influence of the reaction kinetics on the reactor behavior. The following assumptions must be fulfilled [1]:

- The products are instantaneously separated from the reactant(s).
- Mass transfer resistance can be neglected. Additionally, the adsorption – desorption process is fast compared to chemical reaction rate. This means the overall reaction rates are controlled by chemical kinetics.
- Peak spreading and axial dispersion can be neglected.
- The adsorption isotherms are linear.
- The column is homogeneously packed and is operated isothermally.
- The fluid velocity is constant.

The resulting mass balance equation is as follows:

$$\nu_{\mathrm{fluid}} \frac{\partial c_i}{\partial x} + \frac{\partial c_i}{\partial t}\left(1 + K_{\mathrm{H},i}\right) = \nu_i r \tag{3}$$

where ν_{fluid} is the fluid phase flow velocity, c_i is the concentration of component i in the fluid phase, ν_{i} is the stoichiometric coefficient, and r is the reaction rate. The equation can be solved by using the apparent propagation velocity and the method of characteristics [19]. The model of the ideal chromatographic reactor can be used to identify fields of application where a chromatographic reactor gives considerable advantages over conventional reactors. The determination of the reaction kinetics described in Section 7.1 is also often based on the model of the ideal chromatographic reactor. In practice it is difficult to achieve an ideal chromatographic reactor. Nevertheless, its behavior can be approached if the following conditions are met [20]:

- The reaction kinetics are slow compared to adsorption and diffusion processes.
- Particles of small diameter are used for the column packing.
- A column with high efficiency is used.
- The starting material is injected as a short, sharp pulse at low concentration to fulfill the assumption of a linear adsorption isotherm.
- The temperature is well controlled over the whole column.
- The column is carefully packed, and pumps with small flow rate fluctuation are used.

Plate models are based on the assumption that a chromatographic column can be divided into a series of interconnected theoretical plates. In plate models, the axial dispersion is accounted for by the number of plates. The higher the plate number of a column, the smaller is the axial dispersion and the higher is the column efficiency. Two different types of plate models can be used, the Craig model and the Martin and Synge model ($\rightarrow$ Basic Principles of Chromatography). For the modeling of chromatographic reactors only the Martin and Synge model, which neglets mass transfer resistance, has been employed [21], [22].

$$\frac{\partial c_i^j}{\partial x}\left(\varepsilon V_{\text{c}} + (1-\varepsilon)\, V_{\text{c}} \frac{\partial q_i}{\partial c_i}\,|_{c^j}\right) = \dot{V}\left(c_i^{j-1} - c_i^j\right) + (1-\varepsilon)\,\nu_i V_{\text{c}} r \text{ for } j = 1 \ldots N_{\text{c}} \tag{4}$$

where ε is the bed porosity, V_{c} is the plate volume, c_i^{j} is the fluid phase concentration of component i on plate j and N_{c} is the number of theoretical plates.

In comparison to mass balance models only ordinary differential equations have to be solved. Although a plate model has advantages over these models with regard to calculation time, it has some drawbacks. The number of theoretical plates also depends on the components. Therefore, in nonlinear chromatography, using only one plate number for both components significantly reduces the accuracy of the model.

Mass-balance models are based on the differential mass-balance equation. Four models of this type can be found in the literature: the general rate model, the lumped kinetic model, the equilibrium-dispersive model, and a model taking into account mass transfer resistance but neglecting axial dispersion. In the general rate model, all effects of the adsorption and reaction process are analyzed in detail. The following effects are taken into account:

- Axial dispersion
- External mass transfer
- Intraparticle or stationary phase diffusion
- Adsorption – desorption processes

Nevertheless, in most cases a simpler model is sufficient for describing the BCR. The most common approach is the lumped kinetic model. Axial dispersion and mass transfer between fluid and solid phase are taken into account. Different expressions describing the reaction kinetics and the adsorption isotherm respectively can be implemented:

Fluid phase:

$$\begin{aligned}\frac{\partial c_i}{\partial t} &= -\nu_{\text{fluid}} \frac{\partial c_i}{\partial x} + D_{\text{ax}} \frac{\partial^2 c_i}{\partial x^2} \\ &- (1 - X_{\text{cat}})\, k_{\text{eff,ads},i} \frac{6}{d_{\text{p,ads}}} \frac{1-\varepsilon}{\varepsilon} \left(c_i - c_{\text{p,ads},i}\right) \\ &- X_{\text{cat}}\, k_{\text{eff,cat},i} \frac{6}{d_{\text{p,cat}}} \frac{1-\varepsilon}{\varepsilon} \left(c_i - c_{\text{p,cat},i}\right) \\ &+ \nu_i r_{\text{fluid}}\end{aligned} \tag{5}$$

where D_{ax} is the axial dispersion coefficient, $k_{\text{eff},i}$ are the overall mass transfer coefficients of component i, d_{p} is the particle diameter, and X_{cat} is the fraction of catalyst ($0 < X_{\text{cat}} < 1$).

Adsorbent:

$$\frac{\partial q_{\text{ads},i}}{\partial t} = k_{\text{eff,ads},i} \frac{6}{d_{p,\text{ads}}} \left(c_i - c_{\text{p,ads},i}\right) \tag{6}$$

Catalyst:

$$\frac{\partial q_{\mathrm{cat},i}}{\partial t} = k_{\mathrm{eff,cat},i}\frac{6}{d_{p,\mathrm{cat}}}\left(c_i - c_{\mathrm{p,cat},i}\right) + \nu_i r_{\mathrm{cat}} \tag{7}$$

If the catalyst is also the adsorbent ($X_{\mathrm{cat}} = 1$), Equation (6) can be dispensed with and only Equation (5) and (7) are used.

In the equilibrium dispersive model the stationary and the mobile phase are assumed to be in equilibrium, e.g., $c_{\mathrm{i}} = c_{\mathrm{p},i}$. Equation (5) is replaced by:

$$\frac{\partial c_i}{\partial t} + (1 - X_{\mathrm{cat}})\frac{1-\varepsilon}{\varepsilon}\frac{\partial q_{\mathrm{ads},i}}{\partial t} + X_{\mathrm{cat}}\frac{1-\varepsilon}{\varepsilon}\frac{\partial q_{\mathrm{cat},i}}{\partial t} = -\nu_{\mathrm{fluid}}\frac{\partial c_i}{\partial x} + D_{\mathrm{ax}}\frac{\partial^2 c_i}{\partial x^2} + \nu_i r_{\mathrm{fluid}} \tag{8}$$

The stationary phase concentration of the adsorbent $q_{\mathrm{ads},i}$ is given by the adsorption isotherm. The stationary phase concentration of the catalyst $q_{\mathrm{cat},i}$ is calculated from Equation (7), neglecting the term describing the mass transfer kinetics.

In the fourth model the dispersive term in Equation (5) is dropped. The mass transfer coefficient k_{eff} here includes the effect of the dispersion as far as k_{eff} is determined experimentally. Equations (6) and (7) are still valid.

For solving the mass balance equations initial and boundary conditions have to be specified. A common boundary condition is the Dankwerts condition [23].

3.3. Modeling Simulated Moving Bed Chromatographic Reactors

Modeling the continuous SMBCR process requires equations describing the relationship between internal and external flow rates (node balance):

Desorbent node (eluent):

$$Q_{\mathrm{D}} = Q_{\mathrm{I}} - Q_{\mathrm{IV}}$$
$$c_{i,\mathrm{D}}Q_{\mathrm{D}} = c_{i,\mathrm{I}}^{\mathrm{in}}Q_{\mathrm{I}} - c_{i,\mathrm{IV}}^{\mathrm{out}}Q_{\mathrm{IV}} \tag{9}$$

Extract draw-off node:

$$Q_{\mathrm{E}} = Q_{\mathrm{I}} - Q_{\mathrm{II}}$$
$$c_{i,\mathrm{E}} = c_{i,\mathrm{I}}^{\mathrm{out}} = c_{i,\mathrm{II}}^{\mathrm{in}} \tag{10}$$

Feed node:

$$Q_{\mathrm{F}} = Q_{\mathrm{III}} - Q_{\mathrm{II}}$$
$$c_{i,\mathrm{F}}Q_{\mathrm{F}} = c_{i,\mathrm{III}}^{\mathrm{in}}Q_{\mathrm{III}} - c_{i,\mathrm{II}}^{\mathrm{out}}Q_{\mathrm{II}} \tag{11}$$

Raffinate draw-off node:

$$Q_{\mathrm{R}} = Q_{\mathrm{III}} - Q_{\mathrm{IV}}$$
$$c_{i,\mathrm{R}} = c_{i,\mathrm{III}}^{\mathrm{out}} = c_{i,\mathrm{IV}}^{\mathrm{in}} \tag{12}$$

Although a true countercurrent movement of mobile and solid phase is very difficult to realize, the TMB model is often used to describe SMB processes. One reason is that the resulting differential equations are easier to handle and in some cases can even be solved analytically [24]. The hypothetical flow rate of the solid phase in a TMB process can be calculated from the switching time and the length of a column:

$$Q_{\mathrm{S}} = (1-\varepsilon)\,AL_{\mathrm{c}}/t^{*} \tag{13}$$

where Q_{s} is the solid flow rate, L_{c} is the column length and t^{*} is the switching time.

The internal flow rates are given by:

$$Q_j^{\mathrm{TMB}} = Q_j - Q_{\mathrm{s}}/F \tag{14}$$

By combining the node balance and a column model as described above, an SMB model can be built by periodically changing the boundary conditions. As the model for the batch column may be of arbitrary complexity, the resulting SMB models also differ with regard to the effects that are taken into account. An overview of the developed models is given in Table 1.

Using the simpler TMB model to describe an SMBCR has some drawbacks. The periodic characteristics of the SMB process cannot be described (Fig. 8). The resulting axial concentration profile is only an approximation of the profile in the middle of a cycle. The resulting product purities are different. Therefore, it is strongly recommended to use an SMB model.

4. Conditions and Requirements for Preparative Chromatographic Reactors

The first conditions that should be met in order to successfully operate a batch chromatographic reactor in preparative scale have been defined by Matsen et al. [32]:

Table 1. Modeling of simulated moving bed chromatographic reactors

Name	Type	Reaction	Adsorption isotherm	Ideality assumptions ∗	Comments	Ref.
SMB_1	SMB	various	various	DAX, MT		[25]
SMB_2	SMB	various	various	MT		[26]
SMB_3	SMB	various	various	DAX		[27]
SMB_4	SMB	$A \rightarrow B + C$	linear	DAX	numerical dispersion	[28]
SMB_5	SMB	$A \rightleftharpoons B$	linear	AD		[29]
SMB_6	TMB	$A \rightarrow B$	linear		analytical solution	[24]
SMB_7	TMB	$A \rightarrow B \rightarrow C$, $A \rightleftharpoons B$	linear		analytical solution	[9]
SMB_8	SMB, TMB	$A + B \rightleftharpoons C + D$	linear	MT	stage model	[30]
SMB_9	TMB	$A \rightarrow B$	various		analytical solution	[31]

∗ DAX = axial dispersion, MT = external mass transfer, AD = adsorption – desorption processes

Figure 8. Axial profile of the products in an SMBCR at steady state: (SMB model): B: beginning of the cycle, M: middle of the cycle, E: end of the cycle (reaction type: $A \rightleftharpoons B + C$; type of model: SMB_1; adsorption isotherms: linear ($K_{HA} = 0.37$, $K_{HB} = 0.48$, $K_{HC} = 0.26$); reaction kinetics: $r = 1.54 \cdot 10^{-3} \cdot c_A - 1.54 \cdot 10^{-3} \cdot c_B \cdot c_C$)

1) The equilibrium constant for the reaction must be small.
2) Reaction rates should be high enough that separation of products rather than rate of reaction limits the extent of the reaction.
3) At least two products must be formed which are chromatographically separated in the reactor.
4) Reactants must not be separated in the reactor.

Examinations by SARDIN et al. showed that the above requirements can be relaxed [19]. Especially the separation of the starting materials can be overcome by adjusting the mode of operation (see also Chap. 5). As stated by the first rule given above, the application of chromatographic reactors to irreversible reactions ($A \rightarrow B$, $A \rightarrow B + C$, ...) is not as profitable as it is in the case of reversible reactions. Since no reverse reaction exists, the conversion rate cannot be increased by integrating chromatographic separation into the reactor. Therefore, in the following only reversible and consecutive reactions are considered. Besides these reactions, employing chromatographic reactors for product-inhibited reactions is expected to be advantageous compared to a conventional process of reaction and separation in series.

Reaction $A \rightleftharpoons B$. Although the chromatographic batch reactor is often used for the determination of the reaction kinetics of isomerizations, it does not offer any advantages in performing this reaction on a preparative scale. As soon as the product B is separated from the starting material A, it is consumed by the reverse reaction. Assuming first-order kinetics and linear isotherms, VILLERMAUX showed that the conversion in a batch chromatographic reactor does not

exceed that in a conventional fixed-bed reactor [33].

In contrast to operation in batch mode, conversion can be significantly increased beyond chemical equilibrium if a countercurrent reactor is employed. Based on computational studies, TAKEUCHI et al. showed that the conversion for a true moving-bed adsorber consisting of two sections is more than trebled relative to a fixed-bed reactor [9]. Experimental studies on the catalytic hydrogenation of 1,3,5-trimethylbenzene confirmed these results. The reaction was performed in a TMBCR and in a SMBCR. In both cases, experiments and simulation showed that a moving bed chromatographic reactor gave conversion of the starting material significantly exceeding the equilibrium conversion that can be attained in fixed-bed reactors [10], [29], [33].

Reaction $A \rightleftharpoons B + C$. Many studies have dealt with the reversible reaction $A \rightleftharpoons B + C$. For both the BCR and the countercurrent CR, conversion was found to exceed the limit set by chemical equilibrium. Since rules 3 and 4 as stated by MATSEN et al. are fulfilled, the use of chromatographic reactors for this type of reaction seems especially promising. Besides the general criteria given above, certain conditions concerning the adsorption isotherm should be fulfilled. It is clear that the best performance of the reactor can be achieved when the products are more or less strongly adsorbed than the starting materials. This holds for batch reactors [25], [36] and for SMB reactors [37]. Another parameter affecting the performance of SMB chromatographic reactors is the separation factor of the products. In comparison to the SMB separation process, the separation factor has to be larger in the case of the combined process. This can be explained by the formation of the products in sections II and III, i.e., close to the products nodes. Therefore, a smaller part of the apparatus can be used for separation in comparison to the separation process. In the same study, the effect of the reaction kinetics was also examined. It was shown that the use of chromatographic reactors no longer seems promising when the reverse reaction is more than one hundred times faster than the forward reaction [37].

Reaction $A + B \rightleftharpoons C + D$. Unless one of the reactants can be used as the eluent, which reduces the reaction stochiometry to $A \rightleftharpoons B + C$, separation of the reactants must be suppressed. Although separation can be compensated to a certain extent by choice of the operating conditions (see Chap. 5), it is important that the separation factor of the starting materials is small. Additionally, the products should be eluted on either side of one of the reactants [19].

Reaction $A + B \rightarrow R$, $B + R \rightarrow S$. For consecutive reactions like $A + B \rightarrow R$, $B + R \rightarrow S$ the main reason for employing reactive chromatography is to improve the selectivity. In theory, the separation of B and R should suppress the second reaction and the yield of the desired product R should be higher than in a conventional reactor.

The first study of this reaction in the BCR was performed by HATTORI et al. Based on computer simulation, they stated that a significant improvement of selectivity can be expected. The authors of this study assumed identical adsorption of the starting materials. The desired product R was more or less strongly adsorbed than components A and B. The starting materials were injected in pulses [38]. Later these results were confirmed by LIDEN and VAMLING, who also theoretically examined pulsing of components A and B, assuming that only the product R is adsorbed [39].

In contrast, a theoretical study performed by VILLERMAUX showed no improvement relative to fixed-bed reactors if component A is used as eluent while B is periodically pulsed [33], [34]. In 1993 SARDIN et al. [19] resumed the examination of this consecutive reaction in the chromatographic regime. Contrary to HATTORI et al. and LIDEN et al., they allowed different adsorptions of the starting materials. In general the concentration of component A should exceed the concentration of B. Therefore, component A must be injected as a narrow pulse, and component B as a wide pulse. Additionally, component A has to be either less or more strongly adsorbed than B and R.

An experimental investigation of the hydrolysis of glycol diacetate corroborated these theoretical results. Injecting component A at a concentration smaller than that of B makes it impossible to enhance the selectivity. Hence, no experimental proof for an advantage of using the chromatographic reactor has been

given so far. Additionally, for a realistic elution order ($K_{HA} > K_{HR} > K_{HB}$) the improvement in selectivity is rather small in the case of linear adsorption. It totally vanishes for strongly nonlinear adsorption isotherms. In conclusion, performing consecutive reactions of type $A + B \rightarrow R$, $A + R \rightarrow S$ in a chromatographic reactor does not seem to be promising [19].

5. Design of Preparative Chromatographic Reactors

The combination of reaction and separation in one unit operation makes the choice of the adsorbent, catalyst, eluent, and operating conditions more difficult. For an optimal design of a batch process, SARDIN et al. suggested a procedure consisting of six successive steps [19]. In general, the following five steps should be taken:

- Determination of the adsorption isotherm of the starting materials and products without reaction
- Determination of the reaction kinetics
- Development of a numerical model
- Validation of the model by experiments
- Choice of the operating conditions on the basis of numerical simulation

The modeling of chromatographic reactors is addressed in more detail in Chapter 3. In this chapter the choice of the adsorbent and catalyst, the design of the column, and the selection of the operating conditions are described.

Design of the Column. If a solid catalyst is used, the adsorbent and the catalyst have to be packed together. To achieve a homogeneous mixture of the particles, the particle sizes should lie in the same range. Other properties jeopardizing the homogeneity of the packing, for example, density or electrical charge, should also be taken into account. If it is not possible to avoid heterogeneous packing, the catalyst and the adsorbent may be packed in alternating sections. This arrangement should also be preferred when the lifetimes of catalyst and adsorbent differ significantly. However, the effect of the number of segments on the retention time and the conversion of the reaction has to be taken into account. For a given total reactor volume, the influence of this partitioning on the overall conversion rate is shown in Figure 9. A segmentation of 2, for example, indicates a chromatographic reactor separated into two reactor and two separation sections. A heterogeneous reactor with a high partition number operates similarly to the homogeneous reactor. A segmentation of 2 already leads to a considerable increase in the conversion (93.37 %) compared to a conventional reactor (conversion = 67.56 %). As illustrated in Figure 9, a homogeneous mixture of catalyst and adsorbent is favorable, but good results can already be obtained with small partition numbers [25].

Figure 9. Comparison of homogeneous (dashed line) and heterogeneous packing (solid line) of a chromatographic column for a reaction of type $A \rightleftharpoons B + C$; (lumped kinetic model; fraction of catalyst: 0.5; adsorption isotherms: $q_{ads,A} = 1.5 \cdot c_{p,ads,A}/(1 + 0.023 \cdot c_{p,ads,A})$, $q_{ads,B} = 1.86 \cdot c_{p,ads,B}/(1 + 0.025 \cdot c_{p,ads,B})$, $q_C = 1.1 \cdot c_{p,ads,C}/(1 + 0.02 \cdot c_{p,ads,C})$; reaction kinetics: $r = 0.2\,(c_{p,cat,A} - c_{p,cat,B} \cdot c_{p,cat,C}/0.01)$

Choice of Operating Conditions.

Pressure and Temperature. Pressure and temperature have an impact on the reaction and on the separation. Increasing the temperature leads to higher reaction rates but decreases the adsorption, i.e., the retention time. In general, the known rules of equilibrium shifting are valid. For example increasing the pressure in a gas-phase reaction will shift the reaction $A \rightleftharpoons B + C$ towards A [19].

Batch Chromatographic Reactor. In batch operation the parameters injection time t_{inj}, pulse period t_{cyc}, and flow rate must be chosen. These parameters are strongly affected by the reaction kinetics, the reaction stoichiometry, and the adsorption isotherm. Based on the maximum conversion, SARDIN et al. developed simple algebraic equations to calculate the opti-

mum pulse periods [19]. These equations given in Figure 10 are based on the simplifying assumptions of linear adsorption ($K_{\mathrm{H},i}$ = Henry coefficient, see Chap. 3), plug flow, and reaction not effecting the shape of the reactant pulse.

For a reversible reaction of type $\mathrm{A}+\mathrm{B} \rightleftharpoons \mathrm{C}+\mathrm{D}$ the reactants may also be separated because of different adsorption. To increase the conversion, the time of pulse overlap should be as long as possible. This can be achieved by changing the injection mode in an appropriate way. Two possible modes of operation are conceivable. First, as suggested by Sardin et al., the concentrations of the pulses are changed. If a stoichiometric mixture is injected, this also changes the injection time. The injection time of the less strongly adsorbed reactant B can be calculated from:

$$t_{\mathrm{inj,B}} = t_0 \left(K_{\mathrm{HB}} - K_{\mathrm{HA}}\right) + t_{\mathrm{inj,A}} \tag{15}$$

The reactants can also be injected at the same concentration but at different times. One of the reactants can also be used as carrier fluid.

For the consecutive reaction $\mathrm{A}+\mathrm{B} \rightarrow \mathrm{R}$, $\mathrm{R}+\mathrm{B} \rightarrow \mathrm{S}$, the concentration of reactant A must exceed the concentration of B in the reaction zone. Assuming an equimolar feed, component A has to be injected as a sharp pulse either before or after the second reactant B (Fig. 10). The injection time $t_{\mathrm{inj,B}}$ can be estimated by using Equation (15).

Simulated Moving Bed Reactor. Successful operation of SMB chromatographic reactors depends on the correct choice of the internal flow rates and the switching time. In general, the design of these parameters can be divided into three main steps:

- General process layout: determination of the size and the number of columns
- Calculation of a first set of operating parameters by using an analytical process model
- Process optimization based on numerical simulation

In general it is preferable to run a four section SMB to enable recycling of the desorbent. In practice, it may be necessary to remove byproducts and other impurities to achieve the desired product quality. This could be done in an open-loop SMBCR process, in which the recycle stream from zone IV to zone I is eliminated. Byproducts are withdrawn with the effluent at the end of zone IV. This design still offers the advantages concerning conversion rate and product quality discussed above, but it reduces the profitability of the process because of the increased demand for fresh desorbent and the need to refine the effluent. Another argument for open-loop processes is the simplified operation of the SMB unit. If the product in the raffinate stream is not adsorbable, an open-loop configuration consisting of only three sections should be used.

The number of columns and their distribution in the different sections depends on the reaction kinetics and the efficiency of the separation. More columns are required to perform difficult separations, i.e., when the separation factor or the column efficiency is low. Especially for slow reactions it is recommended to increase the reaction zone by adding columns to section III. This can be illustrated by a case study for the SMBCR design for a sucrose inversion reaction. The initial design of the process consisting of eight columns (two columns per section) was changed in two ways:

1) The length of the column was doubled.
2) A third column of same length was added to section III of the initial design.

The resulting production rates are compared to that of the initial design in Table 2. Compared to the initial design, increasing the column length leads to a better ratio of the feed and desorbent flow rates, but the ratio of the feed flow rate to the adsorbent mass significantly decreases. Adding a third column to section III increases the values of both criteria used to calculate the production rate [40].

A first estimation of the flow rates can be made by using separation conditions developed for SMB separation processes. These can be defined on the basis of the ideal model, neglecting axial dispersion and mass transfer resistance. These assumptions allow an analytical solution of the model equations. The ratio of the net fluid flow rate and the adsorbed phase flow rate in each section is given by [41]:

$$m_j = \frac{Q_j t^* - AL_{\mathrm{C}}\varepsilon}{AL_{\mathrm{C}}\left(1-\varepsilon\right)} \tag{16}$$

By using this parameter, the following separation conditions can be defined. The inequalities given here are valid for linear adsorption:

Figure 10. Optimum pulse period for BCR operation

Table 2. Comparison of the production rate for different configurations of the SMB chromatographic reactor

	Process 1	Process 2	Process 3
Process design (column length, reactor partition)	L, 2 : 2 : 2 : 2	$2L$, 2 : 2 : 2 : 2	L, 2 : 2 : 3 : 2
Feed/desorbent	100 %	150 %	144 %
Feed/adsorbent	100 %	66 %	121 %

$$H_{\mathrm{B}} \leq m_{\mathrm{I}} \tag{17}$$

$$H_{\mathrm{C}} \leq m_{\mathrm{II}} \leq m_{\mathrm{III}} \leq H_{\mathrm{B}} \tag{18}$$

$$m_{\mathrm{IV}} \leq H_{\mathrm{C}} \tag{19}$$

These inequalities give the lower limit of the flow rates in sections I and II and the upper limit of the flow rates in sections III and IV. The region of complete separation for section II and III is illustrated in Figure 11. Separation conditions for nonlinear isotherms have also been published [42].

For reasonable process optimization, numerical simulation has to be used. By modifying the switching time and the external fluid streams, the process can be optimized to maximize the conversion rate, product purity, and the feed throughput. Another goal of process optimization is to minimize the consumption of desorbent and the dilution of the products. Figure 12 illustrates the transformation of these optimization goals into a theoretical concentration profile at the end of a switching period. The conversion rate is maximized if the starting material A remains between points 2 and 3. To withdraw both products in a pure form, the concentration fronts of components B and C must not enter zone IV and zone I, respectively. The purity of the desorbent recycle stream is ensured if component C is not allowed to go beyond point 4. Similarly, the purity of the adsorbent is guaranteed if component B cannot reach the area past point 1. If these criteria are exactly met, product dilution and desorbent consumption are minimized.

6. Preparative Chromatographic Reactors

6.1. Applications of Gas Chromatographic Reactors

Besides the applications described below an overview of reactions performed in gas chromatographic reactors is given in Table 3.

Oxidative Coupling of Methane. Ethylene can be produced by the oxidative coupling of methane:

$$2\,CH_4 + 0.5\,O_2 \longrightarrow C_2H_6 + H_2O$$

$$C_2H_6 + 0.5\,O_2 \longrightarrow C_2H_4 + H_2O$$

In a fixed-bed reactor the methane to oxygen ratio must be greater than 20 : 1 to suppress side reactions, primarily the complete oxidation of methane, but this also decreases the conversion of methane. To overcome the small conversion that can be reached in a single fixed-bed tubular reactor, a simulated moving bed chromatographic reactor can be used [53], [54]. Hydrophobic carbon molecular sieve and $YBa_2Zr_3O_{9.5}$ have proved to be a suitable adsorbent and catalyst, respectively [52].

In the first cycle, excess methane is fed into the reaction column. The unconverted reactants are adsorbed in the separation columns. Before methane reaches the outlet of the second separation column, the feed is switched. In the next cycle, methane, desorbed by a carrier gas, is fed into the reaction column. The switching time must be chosen so as to avoid methane break-

through but enable complete regeneration of the adsorption column in the carrier section. The ratio of methane to oxygen in the make-up feed is rather small. According to computer simulation, a methane to oxygen ratio of ca. 1.4 gives the maximum yield of ethane and ethylene [52]. Accordingly, high methane conversion can be achieved in steady state operation. The more strongly adsorbed product can be collected at the outlet of the first separation column.

Hydrogenation of 1,3,5-Trimethylbenzene. The hydrogenation of 1,3,5-trimethylbenzene has been performed in a TMBCR [10], [49], [50] and in an SMBCR [14], [35]. The reaction is equilibrium-limited and no side reactions occur. For both reactor types, the conversion and attainable purities significantly exceed the corresponding values of a fixed-bed reactor. Although the conversion in both processes is nearly the same, using an SMBCR is preferrable. Besides avoiding the problems connected with solid transport, a smaller apparatus can be used [14].

Preparation of Unstable Reagents. On laboratory scale the GCR can be used to produce unstable reagents directly before they are used for synthesis or other reactions. Reactive gas chromatography is useful for the cracking of dicylcopentadiene to cyclopentadiene. A trap at the column outlet is used to condense dicylcopentadiene.

Anhydrous formaldehyde can be produced by depolymerization of trioxane. The gas chromatographic reactor leads to nearly total conversion of the reactant. The product pulses at the column outlet can be directly used in Grignard reactions [20].

6.2. Application of Liquid Chromatographic Reactors

Various reactions, especially in the field of biochemistry, have been performed in chromatographic reactors. A summary of various applications of liquid chromatographic reactors can be found in Table 4.

Isomerization of Glucose. A practical application of running an isomerization reaction in a chromatographic reactor was demonstrated by Hashimoto et al. The reactor concept for the isomerization of glucose is described in Chapter 2. The reaction is catalyzed by immobilized glucose isomerase. The Ca^{2+} form of an ion exchanger is used as adsorbent.

The chromatographic reactor can be compared to two conventional processes. In the first process, the plug-flow reactor is combined with batch chromatographic separation. In the second, the SMB process is used for separation. The performance of the processes is evaluated in terms of the specific desorbent consumption, i.e., the ratio of desorbent flow rate to feed flow rate. Separating glucose and fructose by SMB is superior to the batch process, and producing syrup containing 45 – 65 % fructose using a chromatographic reactor requires the smallest specific desorbent consumption.

Nevertheless a problem in using this process for the production of high-fructose syrup should also be mentioned. For operating a glucose isomerase reactor, Mg^{2+} should be supplied with the solvent to activate and stabilize the enzyme. The Mg^{2+} ions may replace Ca^{2+} ions on the adsorbent, which significantly decreases the separation of fructose and glucose. Therefore, it should be checked if running this process with the Mg^{2+} form of an ion exchanger also offers advantages compared to conventional processes [15].

Inversion of Sucrose. The first known application of the chromatographic reactor in industry is the inversion of sucrose to form glucose and fructose [57]. The reaction is catalyzed by an ion-exchange resin. The products are separated by means of their different adsorption on the ion-exchange resin. Water is used as eluent. The process, developed by Boehringer Mannheim, is run in a batch mode, that is, sucrose pulses are injected at the column inlet. At the column outlet, two fractions with a high fructose and glucose concentration, respectively, can be collected. Afterwards the fractions can be distilled to give highly concentrated solutions or fed to a crystallization unit. A schematic representation of the process is given in Figure 13.

The inversion of sucrose can also be catalyzed by the enzyme invertase. This reaction has been performed in a rotating cylindrical annulus [6]

Table 4. Experimental applications of liquid chromatographic reactors

Reaction	Catalyst	Adsorbent	Reactor	Ref.
Racemic resolution of amino acid esters	immobilized α-chymotrypsin and trypsin	various	BCR	[56]
Acid-catalyzed sucrose inversion	cation-exchange resin	cation-exchange resin	BCR	[57]
Production of dextran	dextransucrase	cation-exchange resin	BCR	[28], [58], [59]
Esterification of acetic acid by ethanol	Amberlyst 15	ion-exchange resin	BCR	[19], [60]
Transesterification of menthyl acetate	acidic cation-exchange resin	acidic cation-exchange resin	BCR	[19]
Hydrolysis of glycol diacetate	OH^-	activated carbon	BCR	[19]
Saccharification of starch to maltose	maltogenase	ion-exchange resin	BCR, CRAC	[7]
Hydrolysis of methyl formate	H^+	activated carbon	CRAC	[5], [61]
Production of Bisphenol A	Amberlyst 31	Amberlyst 31	SMBCR	[13]
Esterification of acetic acid by β-phenethyl alcohol	Amberlyst 15	Amberlyst 15	SMBCR	[12]
Esterification of acetic acid by ethanol	ion-exchange resin	ion-exchange resin	SMBCR	[27]
Enzyme catalyzed sucrose inversion	invertase	cation-exchange resin	SMBCR	[36]
Production of dextran	dextransucrase	cation-exchange resin	SMBCR	[36], [63–65]
Isomerization of glucose	immobilized glucose isomerase	Ca^{2+} form of Y zeolite	CRHFS	[66], [67]

Figure 13. Schematic of a process for the inversion of sucrose

and in a simulated moving bed reactor [68]. The feasibility of performing the inversion in combination with chromatographic separation has been shown in both cases.

Production of Dextran. Dextran is a polyglucose that can be synthesized from sucrose by using the enzyme dextransucrase. Fructose is formed as a byproduct:

$$n\,(C_{12}H_{22}O_{11}) \longrightarrow (C_6H_{10}O_5)_n + n\,(C_6H_{12}O_6)$$

In the pharmaceutical industry dextran is used as a blood volume expander and in the treatment of anemia. In production, a high yield of high molecular mass dextran is desired. The formation of dextran takes place by an insertion mechanism and the dextran chain is dislodged from the enzyme polymer complex by an acceptor molecule. Fructose reduces the fraction of the high molecular mass dextran by acting as an acceptor in the polymerization reaction. Therefore, the fructose concentration should be kept low. This can be done by combining the biochemical reaction and chromatographic separation. For separation an ion-exchange resin in the Ca^{2+} form can be used. The enzyme is supplied with the eluent.

The yield of dextran with molecular mass in excess of 157 000 Da can be increased by using the batch chromatographic reactor (77 %). In a conventional fermentation process only 43.7 % of high molecular mass dextran can be produced. Additionally, fructose can be obtained in high purity [28], [58], [59], [65].

The biosynthesis of dextran can also be performed in an SMBCR consisting of 12 columns. The enzyme is fed into the unit together with the adsorbent. In continuous operation, over 60 % of the produced dextran has a molecular mass exceeding 200 000 Da [63–65].

Nevertheless, some precautions must be taken when employing the SMBCR for synthesizing dextran. First of all particles with an average size not smaller than 450 µm should be used to avoid high pressure buildup in the system. Side reactions can be minimized by previous purification of sucrose. Additional calcium nitrate must be added to the system to overcome the Ca^{2+} loss of the adsorbent during operation.

Production of l-Methionine. The advantage of integration of enzymatic reaction and chromatographic separation has also been shown by using the production of L-methionine as a model reaction. L-Methionine is formed by the enantioselective deacylation of *N*-acetyl-DL-methionine. The reaction is reversible and is inhibited by the product L-methionine and the byproduct acetic acid. It is of special interest because in industry the enantioselective deacylation of *N*-acylated amino acids is a major route to enantiomerically pure L-amino acids. The enzyme, aminoacylase, can be immobilized on an ion-exchange resin that also acts as stationary phase for the separation of the products and the unconverted *N*-acetyl-D-methionine. A sodium chloride solution is used as eluent.

Experiments in the BCR showed complete conversion of *N*-acetyl-DL-methionine. After the reaction takes place in the first 5 – 10 % of the reactor, the components are chromatographically separated. At the column outlet, L-methionine, acetic acid, and the unconverted substrate D-enantiomer can be collected in high purity [69].

Esterification. Ester synthesis is an important reaction in the chemical industry. To achieve high conversion, the reversible reaction has to be followed by separation and recycling of the starting materials. By using a chromatographic reactor both processes can be combined in one unit operation. The feasibility of exceeding chemical equilibrium in a BCR was shown by Sardin et al. [19].

Among others, Kawase et al. applied the concept of SMBCR to esterifications. The production of β-phenethyl acetate was examined at different temperatures. Additionally, the reaction of methacrylic acid and *n*-butanol to form *n*-butyl methacrylate was investigated. Both reactions are catalyzed by an ion-exchange resin in the protonated form. The resin acts not only as a catalyst but also as adsorbent for the chromatographic separation. An open four section SMB configuration was used. High conversion can be reached for the production of β-phenethyl acetate at different temperatures. But for the *n*-butyl methacrylate production only a small ester yield can be obtained although the equilibrium constant is nearly identical to that of β-phenethyl acetate production. This unusual decrease in conversion can be explained by the high separation factor ($\alpha = 3.1$) of methacrylic acid and *n*-butanol. Because of the insufficient reaction rate, acid and alcohol are separated before they react to form the products [70].

Affinity Chromatographic Reactor. Many enzymes need a dissociable coenzyme for their catalytic activity. These coenzymes, for example, nicotinamide adenine dinucleotide (NAD), nicotinamide adenine dinucleotide phosphate (NADP), or adenosine 5′-phosphate (ATP), are expensive and must be regenerated or recycled.

In the affinity chromatographic reactor, the affinity between the coenzyme and the immobilized enzyme can be utilized for dynamic immobilization of the coenzyme. The resulting increase in retention time makes it possible to maximize the cycling number of the coenzyme, that is, the number of product molecules produced by one coenzyme molecule.

The affinity chromatographic reactor was successfully applied to coenzyme cycling by a single enzyme (reduction of propionaldehyde and oxidation of ethanol catalyzed by alcohol dehydrogenase [71]) and to a conjugated double-enzyme system (reduction of pyruvate catalyzed by lactate hydrogenase and oxidation of ethanol catalyzed by alcohol dehydrogenase [72]).

Aromatic Chlorination Reactions. The aromatic chlorination reactions examined by JAEGER et al. clearly demonstrate the enhancement of reactivity and selectivity in a CR. In this reaction an organic substrate, *n*-alkylphenyl ether, interacts with a water-soluble reagent, Cl^-. First the ether is immobilized on a reversed-phase chromatography column. After injection of chlorine water and gradient elution with acetonitrile water, the ratio of *para* and *ortho* products was increased relative to the homogenous reaction. Besides higher regioselectivity, also higher substrate selectivity was found for competitive monochlorination, when the reactants were of different hydrophilic/lipophilic character [73]. A similar result was also found for the base-catalyzed hydrolysis of *p*-nitrophenyl esters [74].

7. Analytical Chromatographic Reactors

7.1. Determination of Rate Constants

Inert-Standard Method. The inert-standard method is most often used for determining reaction rate constants. Assuming ideal chromatographic reactor behavior, the ratio of reactant at the column outlet $n_{\mathrm{r,out}}$ and the amount injected $n_{\mathrm{r,in}}$ is given by:

$$n_{\mathrm{r,out}}/n_{\mathrm{r,in}} = \exp\left[-\left(k_{\mathrm{m}}t_{\mathrm{m}} + k_{\mathrm{s}}t_{\mathrm{s}}\right)\right] \tag{20}$$

Figure 14. Illustration of a chromatogram for the reaction $A \rightleftharpoons B$ in the presence of an inert component

where t_{m} and t_{s} are the residence times of the reactant and k_{m} and k_{s} are kinetic rate constants for forward reaction in the mobile (m) and stationary (s) phase (Fig. 14).

If a known amount of inert reference material (n_i) is added to the injected feed, the peak areas A_{R}, A_{S} can be evaluated to determine an apparent kinetic rate constant k_{app}:

$$\ln\left(\frac{A_{\mathrm{R}}}{A_{\mathrm{I}}}\right) = \ln\left(\frac{n_{\mathrm{R,in}}/S_{\mathrm{R}}}{n_{\mathrm{I}}/S_{\mathrm{I}}}\right) - k_{\mathrm{app}}t_{\mathrm{R}} \tag{21}$$

where S is the detector sensitivity and t_{R} is the total column residence time of the reactant. By measuring k_{m} in a batch reactor, k_{s} can be determined from:

$$k_{\mathrm{app}} = \left(\frac{t_{\mathrm{m}}}{t_{\mathrm{R}}}\right)k_{\mathrm{m}} + \left(\frac{t_{\mathrm{s}}}{t_{\mathrm{R}}}\right)k_{\mathrm{s}} \tag{22}$$

By employing a void column between two packed columns, k_{m} and k_{s} can be measured simultaneously. Measurements with varying void volume and flow rate can be evaluated to determine the kinetic rate constants:

$$\frac{A_{\mathrm{p}} + A_{\nu}}{A_{\mathrm{I}}} = C_1 - C_2 \exp\left[\left(-k_{\mathrm{m},\nu}t_{\nu} + k_{\mathrm{m,c}}t_{\mathrm{c}} + k_{\mathrm{s}}t_{\mathrm{s}}\right)\right] \tag{23}$$

where the peak area of void product formation is given by A_{ν}, C_1 and C_2 are empirical constants, t_{ν} represents the residence time in the void column, and $k_{\mathrm{m},\nu}$ and $k_{\mathrm{m,c}}$ are the mobile phase kinetic rate constants in the void and the packed column, respectively [75], [76].

If the assumption of the ideal chromatographic reactor no longer holds, equations to evaluate the chromatogram taking into account adsorption – desorption kinetics or axial dispersion can be found in the literature [77].

Evaluation of the Overall Elution Profile. Although the inert-standard method is commonly used, sometimes the search for a suitable standard is time-consuming. Calculation of the peak area of the reactant may also be difficult. By applying the first statistical moment the overall elution profile can be evaluated for the determination of kinetic rate constants in the case of a pseudo-first-order chemical reaction [78]. Another method that can be applied here is the Fast Fourier Transform technique [79].

Stopped-Flow Method. For catalytic reactions, the stopped flow method can be used to lengthen the overall reaction time. Additionally, limitations by mass transfer resistance and slow adsorption – desorption processes may be overcome. The products that are formed during the stopped-flow period form sharp peaks superimposed on the continuous chromatogram (Fig. 15).

Figure 15. Illustration of a stopped-flow chromatogram for the reaction A ⇌ B

By stopping the flow twice, the resulting product peaks can be evaluated to give the reaction rate constant:

$$\ln\left(\frac{A_1}{A_2}\right) = k_s f_s\,(t_2 - t_1) + \ln\frac{\sinh\,(k_s f_s \nu_1)}{\sinh\,(k_s f_s \nu_2)} \quad (24)$$

where f_s is the fraction of the residence time of the reactant being adsorbed on the surface. The stopped-flow interval is 2ν, centered at t [1], [80].

Conditions and Requirements. The inert-standard method can be used for determining an apparent rate coefficient lying in the range between $3 \times 10^{-6}\,s^{-1}$ and $2 \times 10^{-1}\,s^{-1}$. Generally, the most accurate results are obtained when k_{app} is in the middle of this range, i.e., from $10^{-4}\,s^{-1}$ to $10^{-2}\,s^{-1}$. For slower reactions, other techniques such as the stopped-flow method must be used.

The examination of first-order or pseudo-first-order reactions is especially attractive. The experiments can be easily evaluated by using analytical solutions that determine the amount of product at the column outlet.

To distinguish between the product peak and inert peak, both components have to be sufficiently separated. This can easily be achieved with a separation factor of 1.5, but the time required for analysis is unnecessarily prolonged if the separation factor is too large. Langer and Patton suggest choosing the inert substance such that the separation factor is in the range between 1.5 and 2.0 [1].

7.2. Enzymatic Reactions

Determination of Reaction Kinetics. The chromatographic reactor has been successfully applied to determining the reaction kinetics of the hydrolysis of *o*-nitrophenyl-β-D-galactopyranoside with immobilized lactase in a microreactor. The enzyme was immobilized on porous glass beads. Besides the possibility of using already available equipment with only small modifications, the speed and ease of obtaining reproducible data are advantageous. By this method to measure enzyme activity different parameters that influence the immobilization efficiency can be easily screened [81].

Analysis of Enantioselectivity. Enantiomerically pure components can be produced by chiral resolution of the racemic mixture catalyzed by an enzyme. For process optimization the enantioselectivity must be examined under different operating conditions. This can easily be done by the method presented by Wu [82]. The number of enzyme molecules in the column has to exceed the total enantiomer input to fulfill the assumption of constant enzyme concentration.

The analysis of the peak areas at the column outlet are used to calculate the conversion of each enantiomer. The enantioselectivity is given by:

$$E = \frac{\ln\left(1 - X^{R}\right)}{\ln\left(1 - X^{S}\right)} \quad (25)$$

where X^R and X^S are the individual conversion of the R and S enantiomer, respectively.

7.3. Characterization of the Stationary Phase

Determination of Residual Oil Saturation. The amount of residual oil in a porous rock structure can be determined by injecting an ethyl acetate pulse into the well. Water acts as mobile phase, the oil in the porous rock is the stationary phase. Ethanol is formed by hydrolysis of

the tracer ethyl acetate. It is most soluble in water, whereas the tracer is soluble in both phases. After reversing the flow, the difference between ethanol and ethyl acetate reaching the well head is measured. As the difference corresponds to the residence time in the oil phase, it can be used to obtain the residual oil saturation in the rock [83], [84].

Detection of Reactive Zones in Chromatographic Columns. Reaction chromatography can be used to diagnose the existence of reactive sites in the adsorbent. An example is hydroquinone oxidation, which can be used for the detection of metal ions adsorbed on silica surfaces. The existence of active sites can be proved if decreasing the flow rate leads to increasing product peaks. The positions of the active sites can be determined by reversing the direction of flow [85]. The distribution function of active sites on a catalytic surface can be determined using stopped flow chromatography [86].

Determination of Temperature Zones. Irregularities in the temperature profile along the column can be easily detected and located in the chromatogram. The increased product formation in the hot zone caused by higher reaction rate can be identified as an extra peak in the product curve. The sensitivity of this method depends on the difference of the activation energy and the differential molar heat of vaporization of the reactant from solution. The hot zone can be most easily detected when the difference is high and the retention times of reactant and product differ significantly. A practical application of this method has been demonstrated for trioxane depolymerization [1].

Determination of Void Zones. Void zones also lead to irregularities in the chromatogram. In a void zone the reactant and the product are not separated from each other. Accordingly, the void zones can be identified as a small peak in the chromatogram. The dissociation of endodicyclopentadiene can be used to determine heterogenities in the column packing [87].

7.4. Examination of Fast Equilibrium Reactions

For fast equilibrium reactions like isomerization, enantiomerization, and intramolecular bond rotation, separation is affected by simultaneous reaction. The degree of separation depends on the reaction rate. For very fast interconversion, only one peak will appear at the column outlet. Two peaks can be observed with decreasing reaction rate. The retention time of the two peaks tends towards the corresponding elution of the pure components, the slower the isomerization takes place [88]. Examples for kinetic studies of this reaction are the separation of tautomers of β-diketoesters [89], *cis – trans* proline isomerization [90], and the separation of alpha and beta anomers of muramyldipeptide I [91].

To achieve separation, operating conditions such as temperature, mobile phase composition, and flow rates, must be chosen so as to decrease the interconversion rate. MORIYASU et al. achieved the separation of keto and enol tautomers by lowering the temperature [92].

7.5. Examination of Solvent Effects

To examine solvent effects with a gas chromatographic reactor, the solvent must be impregnated on a solid support. The reaction rate can be determined by measuring the appearance of product and the disappearance of starting material at the column outlet. Additionally solute – solvent interactions can be examined. Examples given in the literature include the determination of infinite-dilution activity coefficients.

Carrying out the chemical reaction does not lead to contamination of the solvent. This means it can be repeatedly used for other reactants or reactions. By preparing columns with different stationary phases, different solvents can be screened and the solvent choice can be optimized. Another advantage of the application of the GCR is the near complete suppression of side reactions by choosing appropriate operating conditions. Side reactions that do still occur can be easily detected. One example of the GCR being used for analyzing solvent effects is the investigation of the dissociation of endodicyclopentadiene to cyclopentadiene [93]. It was

found that the reaction rate increases with increasing liquid-phase polarity which, however, favors side reactions.

The effect of different solvents on reaction kinetics has also been examined for the thermal dissociation of several isomeric methylcyclopentadiene dimers [94].

1. Introduction

Custom synthesis can be defined as the business comprising those operations associated with molecule building performed by a third party vendor on a service basis on the behalf of a specific customer having typically no legal affiliation with him.

Custom synthesis is best viewed as one of the multiple segments making the outsourcing space. In its broadest sense this space can be defined as covering all services and products provided on a one-to-one basis by a vendor for the specific use of a given end user. Within this frame, the latter, rather than performing certain activities in-house through his own capabilities and assets, delegates these to a third party.

Although defined as covering only molecule building activities, custom synthesis represents in itself a very complex field made by innumerable segments and subsegments, as illustrated in Figure 1.

These reflect the multitude of situations and variants that can be observed including:

- The type of input supplied, either a service such as the development of an optimized process – technology package ready to be transferred or a product that can be both an intermediate or the final compound.
- The position in the life cycle of the customer end product covered by the custom synthesis relation being considered, namely early and later phase development, launch, maturity or sunset (at peak sales or in their final decline stages). The position of the product in its life cycle has obviously implications in terms of elements such as quantities supplied as well as customer expectations vested in his vendors.
- End-user industry served, e.g., agrochemical, personal care, pharma, electronic chemicals. Molecular structures, volumes as well as regulatory and vendor qualifications hurdles vary widely depending on the application considered.

In custom synthesis both the group of customers and that of vendors is very broad reflecting the extreme fragmentation of this field and the number of situation encountered. Similarly, contractual conditions associated with custom synthesis range widely depending on the scope of the vendor – customer agreement. As an example the agreement can be either restricted to the conversion on a cost-plus basis of a given raw material supplied by the customer or may cover the development by the vendor of the technology – processes required to produce cost effectively the end molecule required by the customer.

It is therefore no surprise that given this extreme fragmentation the precise boundaries and size of the custom synthesis space are ill defined — the industry turnover ranging depending on estimates between more than \$ 50×10^9 to just \$ $6 – 7 \times 10^9$ when limiting its scope to the life science outlet.

Although definitions and boundaries differ depending on the source considered, some traits clearly differentiate custom synthesis from other segments of the chemicals industry. These include:

Figure 1. Subsegments of custom synthesis

- The one-to-one relation existing between the vendor and his customer. The first supplying the product or the service on an exclusive basis to the end user who typically is either the originator or owns the full rights on the chemical compound.
- The service type dynamics of the business, the vendor engaging in the supply of the compound at the specific request of a given customer. This means that the vendor is entirely dependent on his customer and has either no or limited control on the ultimate fate of the business should the product be withdrawn from the market or should the customer elect to change of supply source.
- The limited transparency of the business. Customers typically insist to maintain dealings with their vendors confidential, probably as a tactic to increase their leverage.

Although often associated with just fine chemicals and/or the life science industry, custom synthesis covers all segments of the chemical industry and of its outlets and those of its users. Custom synthesis agreements can be observed both for large volume commodity chemicals supplied in tonnages of hundred or thousand of tons and for substances produced on the microgram scale, as an example screening libraries going to the pharma and agrochemical industry. The end-user base for custom synthesis is similarly extremely broad. It comprises both integrated end users having own chemical production facilities electing to outsource part of their requirements, as an example to avoid in-house investments as well as virtual companies having no option but to rely on a third party supplier for their molecular requirements.

The vendor slate is equally extremely broad, in total several thousand companies supplying custom-made chemicals. These include both large diversified chemical companies having developed a base in custom synthesis as a strategy to leverage their technology base and/or to load assets as well as players for whom custom synthesis is their main business. The number of players in custom synthesis has increased since 2000. As an example China and India have become increasingly important forces in custom chemicals, particularly in some product groups, their entry having contributed to exacerbate competitive intensity levels in depressing thereby profit margins in the industry.

2. Genesis

The outsourcing phenomenon dates back from the 1950s. It is finding its roots in the automotive industry having gradually abandoned the full vertical integration model epitomized by the famous “Ford Rivière Rouge” site. On the Rivière Rouge site the Ford Motor Company had built a fully integrated production system able to transform iron ore and coal into complete automo-

biles! However, such an integrated model has been gradually superseded by rather delegating to external suppliers the production and later also the development of selected components or operations of an increasing number of tasks.

The drivers behind the decision to outsource are multiple, including:

- Focus on areas of core competence also often referred to as those operations and processes allowing to effectively create value and providing scope for competitive edge — manufacturing being rarely considered as one of these — contrary to product design, R& D, or marketing.
- The new metrics adopted by management following increasing scrutiny by investors and financial analysts pushing for a more effective use of capital. Within this frame options to avoid in-house investments in fixed assets such as production plants are more and more embraced, outsourcing to a third party being one of these. This drive towards reducing the asset base has prompted some companies to divest part if not their entire manufacturing network.
- The strategy of companies to avoid building up their own fixed cost base — rather electing to outsource some operations. Within this frame outsourcing is viewed as a convenient tool to shift costs to an external entity, allowing to achieve enhanced financial flexibility levels.
- The desire to tap the best available resources when and if required, avoiding building an own resource base that would be difficult to maintain fully loaded and alert.
- Advances in information technology (IT) and communication systems combined with more sophisticated management tools allowing to enhance the transparency of internal operations including in terms of activity costs, enabling also to compare these with alternative options such as outsourcing.
- The emergence of viable alternatives to in-house operations, several vendors focusing their activities around outsourcing services making these their core business. An example is Lonza (Basel, Switzerland) in fine chemicals molecule building.

Parallel to this, a number of new entrants applying innovative business models calling for extensively outsourcing most of their operations have increasingly started to challenge the dominance of traditional fully vertically integrated companies, forcing these to reassess their mode of operations including in terms of sourcing. Examples in the pharmaceutical sector include most emerging pharma players — also often referred to as "biotech" companies — whose focus is on discovery and development.

Similarly to most other segments of the outsourcing space the origins of custom synthesis are difficult to pinpoint to any specific event. The first indications and reports on custom synthesis related activities date from the 1960s and 1970s. At that time several end users — including some large pharmaceutical companies — saw the demand for their products surge, outstripping their own synthesis capacity. Parallel to this, the paradigm calling for backward integration among several end user outlets for chemicals such as pharma, agrochemicals, flavors and fragrances,. . .started to become increasingly challenged. This has led several chemical users to rely on third party vendors not just for "standard" catalogue items but also on products made for their exclusive use under the frame of custom synthesis supply contracts.

One of the first documented examples of custom synthesis appears to be represented in the late 1970s — early 1980s by the supply of cimetidine intermediates to SmithKline & French (Philadelphia, USA). At that time the sales volumes for cimetidine, the first antiulcer drug having truly curative effects allowing to avoid surgery, literally exploded, outstripping the most widely optimistic assumptions. Facing the prospect of losing sales volumes due to short product availability because of chemical synthesis bottlenecks, SmithKline & French contacted various fine chemicals vendors including Fine Organics (Seal Sands, UK), Heico (Philadelphia, USA) and Lonza (Basel, Switzerland) asking them to supply on an exclusive basis selected cimetidine precursors such as the imidazole or the cysteamine intermediate. The overall concept and business model applied was simple, the originator providing to the vendor the process, the vendor applying it in his own facilities. This was corresponding to a win-win scheme:

- The vendor taking advantage of the infrastructure on hand.

- The customer avoiding to invest in own capacity whilst securing immediate access to capacity if and when required.

Since then the custom synthesis area has greatly evolved and grown. Landmarks in this development path include:

- The pioneering efforts of some companies like Lonza in developing the concept of custom synthesis positioning themselves as a credible alternative to in-house chemical operations.
- The growing role played by start-up companies in various end user segments such as pharmaceuticals. Although the share of start-ups in total pharmaceutical sales is still modest - not exceeding a few percentage points of the global pharma turnover $> \$\ 500\ 10^9$– a growing number of new molecular entities (NME) are stemming from these companies (see Fig. 2.).
  As these have no own synthesis capacity, they have no choice but to rely on third party suppliers for their chemical requirements.
- The globalization and increasing transparency of chemical markets combined with the mounting financial pressures facing chemical companies and chemicals users. These are more and more expected to compress their fixed cost base and in parallel reducing capital expenditure (capex) outlays. The industry is gradually starting to pay more attention to concepts such as economic value added or ability to ultimately earn acceptable returns on capital invested. Within this frame a growing number of end users are electing to source their chemical requirements from third party vendors rather than continuing to produce in-house. The rationale behind such outsourcing include on the behalf of the customer considerations such as access to key technologies, capex reduction, cost structure optimization as well as time-to-market imperatives.

Compared to the original days, the custom synthesis industry has become increasingly segmented. As an example, in addition to full scale production of synthetic compounds — be these organic or inorganic, it now covers also biological products obtained by either microbial formulation or animal cell culture as well as related development services:

- Mycophenolic acid — an immunomodulator used to prevent rejection used in organ grafts. The compound, originally developed by Syntex — now Roche (Basel, Switzerland) and obtained through microbial fermentation, has been for long produced on a custom basis by Antibioticos (Settimo Torinese, Italy), a company having a long tradition in fermentation.
- Eternacept, the fusion protein making the active ingredient of Enbrel — one of the most innovative drugs for treatment of degenerative arthritis — is obtained by cell culture. The cultivation has been largely sourced out through custom production agreements between the originator Immunex (Seattle, USA) and Boehringer Ingelheim (Ingelheim, Germany). Amgen (Thousand Oaks, USA) and Wyeth, marketing the product have over the years invested in own capacity.

Although traditionally limited to the supply of full scale volumes, a growing segment of the custom synthesis space is represented by activities associated with the supply of products and services relating to molecules still in early or late development. These include the:

- Supply of libraries of compounds developed at the specific request of a given customer in view of their screening for biological activity to identify possible lead development candidates. These libraries can be either "random" or "focused" — namely revolving around selected molecular platforms, quantities involved rarely exceeding the microgram scale.
- Synthesis of analogues to the original lead compound aiming to obtain suitable development candidates. The synthesis and design of these analogues largely revolves around quantitative structure-activity relationship (QSAR) tools. Such capabilities and services are increasingly offered by third party vendors, examples including Evotec-OSI (Cambridge, UK), AMRI (Albany, USA) or ChemBridge (San Diego, USA).
- Supply of small scale lots of either the final chemical or of its related intermediates in view of their testing on the field. Vendors like ChemShop (Tilburg, Netherlands), Onyx (Newcastle, UK) or Ricerca (Ohio, USA) having made this area their prime focus.

Figure 2. Share of NME by type of originator

- Provision of development services associated as an example to the elaboration of the chemistry, manufacturing, and control (CMC) file, the technical package for compounds still in the development pipeline as well as the design of second generation processes for chemical substances already on the market. The latter corresponds to the request of a customer to a third party vendor to develop a new process allowing to either reduce overall production costs or extend the period of effective patent exclusivity leveraging process related intellectual property (IP).

Another important factor in the overall evolution of the custom synthesis space is the emergence of vendors providing a full range of outsourcing services to the customer — sometimes going beyond molecule building. Examples include in pharmaceuticals, vendors in India such as Matrix (Hyderabad) and Suven (Hyderabad) aiming to become full fledged pharma Custom Research and Manufacturing (CRAM) partners providing to their pharma customers services covering the entire spectrum of molecule building activities — from microgram up to multiton scale — as well as dosage form manufacturing.

In the 1990s industry analysts predicted growing polarization between at one extreme virtual companies entirely outsourcing their chemicals operations and at the other end service providers having no own products but rather supplying on a service basis chemicals to the other cluster of companies. The model postulated that chemical operations are best left to specialized vendors for whom chemical production is their core business — enabling them to achieve better economics through a combination of experience as well as enhanced capital efficiency. Based on these postulates there have been predicaments from the financial community that several chemical companies and chemical users would be better off by entirely farming up their molecule building activities, divesting or spinning off their chemical assets rather relying on specialized third party vendors.

In doing so companies would embrace a "virtual" model delegating to selected vendors major parts if not their entire chemical assets and operations. However, barring a handful of exceptions observed mainly in Japan, hardly any player has moved so far as to fully embrace the virtual model. Rather, most chemical companies and chemical users have now adopted the concept of strategic sourcing where all options to secure access to the required chemical input are systematically evaluated on a which is the best basis. Within this frame neither in-house production nor outsourcing–custom production are viewed as ends perse.

To this end various considerations are taken into account in formulating the sourcing decision, including:

- *Philosophy of the customer and his commitment to chemical operations*. Within this frame European companies tend to be less open to outsourcing than their US counterparts, reflecting their historical roots in chemistry.
- *Position of the product in its life cycle*. The drivers behind outsourcing varying widely between mature to aging products where cost represents a key driver and development compounds for whom availability and time-to-market are critical considerations.

- *Type of technologies and capabilities associated with the production of the compound considered*. Depending on the circumstances very special technologies are either insourced given perceived scope for competitive advantage — or outsourced in order to avoid commit investments in own dedicated assets and resources.
- *Resource availability*. Customers almost invariably tend to prefer loading their own assets and maintain their own staff busy rather than outsource operations and engaging in harsh internal restructuring steps. For example, following the wave of mergers observed in the late 1990s among life science companies an overcapacity situation has emerged. This has resulted in setbacks for custom synthesis service providers as customers have tended during lean times to insource.
- *Security of supply*. Several end users still viewing outsourcing of chemical production more risky compared to in-house operations.
- *Overall economics*. Customers almost invariably tend to compare their own variable costs with price offers of third party vendors, these having necessarily to include full costs incurred plus an acceptable markup.
- *Market access considerations*. Some countries mandate, at least for selected product groups such as agrochemicals and pharmaceutical, local content requirements, de-facto imposing to the marketer to rely on third party suppliers located in the country to be penetrated.
- *Tax optimization strategies*. Here companies leverage transfer prices among different countries — the objective being to log the largest possible share of profits in the lowest tax country. Obviously, within this frame outsourcing requires a careful assessment of its possible impact and portability with tax considerations.

3. Supply Structure

In total probably several thousand companies provide custom synthesis related services. These comprise both small family-owned vendors such as Pressure Chemicals (Chicago, USA) or ChemShop in the Netherlands to divisions of diversified chemical groups, e.g., Dow Pharmaceutical Services and Lonza Exclusive Synthesis. Depending on the supplier custom chemicals can be either the sole business or part of a broader business portfolio.

The emergence of companies specializing on supplying on a custom basis chemical related inputs is to be viewed within the broader context of the reshaping of the chemical industry.

This reshaping has been prompted by drivers including:

- Increasing shareholder activism.
- Chronic inability of most chemical companies to recover their cost of capital over a full economic cycle.
- Surging operating hurdles.
- Emergence of new sets of competitors.
- Evolving customer or more broadly key stakeholders expectations.

As a result the chemical industry has undergone a period of major change and consolidation leading also to the emergence of more focused models such as:

- Chemical utilities, also often referred to as commodity chemical companies focusing on large volume products obtained directly out of basic feedstocks — their value proposition revolving around low cost position reflecting economies of scale and superior access to key feedstocks. Examples of such companies include Methanex (Vancouver, Canada), SQM (Santiago, Chile) or Sabic (Ryadh, Saudi Arabia).
- Product and technology specialists centering their activities around selected product trees and/or technology know-how such as fluorination, nitration, or oxo condensations. Their product range is largely focused on forward commodities and value-added intermediates, levers for value creation being represented by distinctive technology capabilities and focus. Examples of such type companies are by Lonza Polymer Intermediates, Degussa Building Blocks or Rhodia Diphenols.
- Application specialists whose emphasis is on formulated products sold on a performance basis. Key success factors among this set of players largely evolve around application know-how and technical services. Examples of such companies include life science groups, coating and functional food additives suppliers.

- Chemical solution providers whose business is to offer to customers an alternative to own chemical production or formulation activities. Rather than compounds supplied on a specification basis, this set of players is providing customized services to their customers. In doing so, they leverage superior operation management and production economics. Examples of players in this field include in molecule building ChemShop and Lonza Exclusive Synthesis, GE-Betz (Allentown, USA) and PPG (Pittsburgh, USA) providing respectively turn-key chemical solutions in industrial water treatment and automotive coatings.

In addition to Western third party vendors, an increasing number of companies located in China, India, as well as other emerging regions such as CIS, are active in the broadly defined custom chemicals space. Their entry corresponds to the increasing globalization of the chemical industry as well as the quest among customers for the most competitive source:

- CIS has emerged as one of the most important sources of custom-made chemical libraries and early phase custom synthesis services. This country having access to a large molecular diversity pool as well as to substantial synthesis talent. Examples of service providers finding their roots in CIS include ChemBridge (San Diego, USA) as well as Chemical Diversity (San Mateo, USA).
- India is more and more considered for the supply of custom-made intermediates. A growing number of chemical companies trying to build a base in custom chemicals, their value proposition revolving around low labor costs, limited labor and environmental hurdles as well as access to an ample chemically trained work force. Examples of such players include Dishman (Ahmedabad), supplying part of the eposartan bulk requirements of Solvay Duphar, Matrix, or Suven.
- China is taking an increasing role as manufacturing hub for the global chemical industry. Its focus has been traditionally on standard–catalogue products, some companies such as Wuxi Pharmaceuticals (Wuxi) having made out of this business their core activity.

By and large the main attractiveness of Chinese and Indian based vendors results from lower perceived unit prices largely reflecting a combination of cheap labor costs and limited capex outlays compared to their Western counterparts.

The supplier slate in custom chemicals is also extremely heterogeneous in terms of size, comprising both large competitors having custom chemicals sales in excess of $ 300×10^6 such as DPP (DSM Pharmaceutical Products, Heerlen, The Netherlands) or Lonza and smaller companies with a turnover of less than $ 10×10^6, possible examples including Ash Stevens or ChemCon (Freiburg, Germany). Most often smaller competitors tend to focus on niches revolving around selected products or technologies, whilst their larger counterparts offer a broader range of services sometimes positioning themselves as full "molecule building" service providers.

4. Customer Base

The group of customers for custom synthesis is extremely broad. It ranges from major multinational companies such as Procter & Gamble (Cincinnati, OH, USA) or DuPont (Wilmington, DE, USA) to start-up companies like Nicox (Nice, France) or Vertex (Waltham, USA).

The custom synthesis requirements and expectations of these players range widely, including:

- Back-up supply agreements where the customer seeks to secure access to a second source to ensure continuous access to his chemical input requirements.
- The full outsourcing of chemical input requirements from selected third party vendors, the customer having no option but to rely on external sources for his chemical needs. Examples include Wyeth and Gilead,both in pharmaceuticals.

The type of product and input outsourced also spans over a wide spectrum covering:

- The supply of early phase lots or research quantities, as an example screening libraries.
- Intermediates as well as the final compound ready to undergo the formulation/ physical processing step — not requiring to undergo any further molecule building transformation.

Depending on the type of inputs required customer expectations vested in the custom synthesis vendor vary. Most often low delivered unit prices represent the overriding factor for noncritical items such as mature to aging end products where the emphasis is on cost minimization. On the contrary for products in the development phase timely availability, responsiveness, and flexibility represent the critical success factors.

Similarly, the mode of interaction between customers and vendors varies widely, with three main models emerging. These are represented by:

– The traditional "you-against-me" type of interaction where the customer systematically asks bids for every product outsourced from a large number of vendors. The overall driver being to extract all possible price concessions by skillfully playing one vendor against the other.
– The partnership setup where customers rather enter into preferential dealings with one or two main lead — tier 1 — vendors who act as extensions of the customer own operations. In such a setup the customer delegates entire parts of his chemical development and full scale supply requirements to these vendors — setup comparable to the one embraced by the automotive industry. This implies that the retained vendors are granted the right of first refusal on all (most) new chemical requirements of the customer. In exchange of this they are asked to provide preferential treatment of the customer as well as pledging to continuous cost reduction targets to be shared with the customer. Although widely advertised in the industry, examples of genuine strategic partnership agreements between end users and vendors are relatively rare in custom synthesis.
– "A-la-carte" dealings where the customer defines and selects a short list of e.g. five to ten vendors, prequalifying them in terms of range of capabilities, compatibility with own systems and procedures, as well as ability to effectively interface with own staff. In such a setup the customer asks for each project/product offers from two to three vendors, selecting these on a which is the best basis. This à-la-carte mode of interaction appears to be increasingly embraced by the industry.

5. Contractual Relations

Custom synthesis often represents a business where prices of products and services provided are set on a cost-plus basis, the profit margins eventually achievable depending on:

- The overall competitive position including compared to the customer own in-house capabilities.
- The ability of the vendor to efficiently manage his own cost base.

Within this frame it is important to note that typically the customer has a good understanding of the costs involved to produce the inputs he requires, these insights reflecting either his own experience or the price offers received from other vendors. Levers available to vendors to achieve above average returns include:

- Proprietary technologies or IP position, making them the obliged partner to the customer, Lonza Biotechnology with its patented GS (glutamine synthase) cell culture expression system in custom biopharmaceuticals representing a notable example.
- Short capacity availability restricting thereby the customer degrees of freedom in exerting price leverage.

Various pricing schemes can be observed in the custom synthesis space including:

- Fixed price contracts.
- Cost-plus, where the vendor is granted a preagreed markup over and above his own costs.
- Profit sharing, where the vendor receives a fraction of the sales (profit) associated with the end product he is dealing with.

The duration so as the terms of the agreement can vary widely, ranging from yearly (monthly) agreements to multiyears, e.g., three to five years agreements. Depending on the contract the customer can provide for just indicative volume targets, e.g., 80 to 120% of a certain predefined nonbinding target, or settle for firm take-or-pay provisions where the vendor is guaranteed a certain revenue stream irrespective of the quantities of inputs actually supplied. Examples of such take-or-pay agreements include the reservation

fees paid by pharma customers to secure access to biopharmaceutical production capacity following the aftermath of the Etarnecept – Embrel case where supply had been inadequate to meet demand.

Very often a key pricing determinant in custom chemicals is represented by the unit labor and capacity costs incurred by the vendor. Either implicitly or explicitly these are used in the pricing offer provided by the vendor to the customer. In development work a key driver of pricing is the so-called full-time-equivalent (FTE), defined as the price at which the vendor is offering a unit of time (e.g., one hour, one day, a week or a year) for a staff member. Rates applied vary widely. As an example in 2005 FTE observed for process development work ranged from $ 50 000 per person and year to over $ 250 000 per person and year depending on:

- The location of the vendor. The lowest rates tending to be applied by vendors located in China or India whereas North American based companies are among the highest.
- Reputation of the vendor and his track record.
- Range of services included. Some vendors excluding from FTE quotations the supply of raw materials/ reagents, whilst such costs are included in the offers of other suppliers.
- Qualification of the personnel. Some vendors applying identical rates for all their staff contrary to other who differentiate between the rates applied for a Ph.D. and staff without academic degrees.

Similarly for pilot- and full-scale production a key parameter is represented by the equipment hours — namely the cost per unit of time associated with operating a given piece of equipment. Here too the pricing offer of the vendor can be either fully transparent explicitly reporting the estimated hours of utilization for each piece of equipment multiplied by the associated unit costs or rather "flat-inclusive" providing no detail.

In terms of contractual conditions the customer typically insists with his custom chemicals vendors for:

- Full confidentiality, the supply relation being rarely advertised as the customer prefers to keep it secret. The reasons behind such secrecy are multiple, being associated mainly with fears of IP and data leakage. Another reason often indicated relates also with the desire of the customer to keep the supply structure opaque in order to enhance his bargaining position vis-à-vis vendors.
- Complete control and ownership on all IP that may be developed by the vendor as part of the custom chemical supply relationship. In this respect the customer typically demands for being granted automatic licensing right on all know-how and inventions that may be brought by the vendor. Also, most often the customer will request his vendors to refrain from using this know-how for products and/or accounts that may be in direct or indirect competition with him.
- Share all cost savings that may result from learning curve effects and/or improvements brought by the vendor.
- Diligently apply the processes specified in the custom synthesis contract — any change having to be properly documented, reported and approved by the customer before implementation. The adherence to such standard operating procedures (SOP) is particularly critical for chemicals going to applications characterized either by exacting specifications (e.g., electronic chemicals) or extensive regulatory hurdles (e.g., pharmaceutical fine chemicals).

Depending on the contractual agreement, the raw materials can be either supplied by the customer to the vendor or sourced directly by the vendor following the specification set of the customer.

The duration of the contract is also extremely variable, ranging from a few months to multiyear (e.g., five to seven) agreements. Shorter contracts tend to be typical for relatively simple processes that can be easily transferred from one source to the other, as for banal chemical transformations. For more complex processes or where the production site needs to be inspected by the regulatory authorities longer contracts are typically the rule.

Depending on the product, associated volumes as well as on the specific customer the number of custom synthesis vendors retained for a given compound differs. Often small volume products are outsourced to just one vendor, security of supply being managed by maintaining adequate back-up inventories calculated based

on the lead time for developing an alternative source. Multiple sources are established for large volume products as well as molecules generating large sales. For these a lead source providing for, e.g., 70 – 80 % of total volumes is complemented by a back-up vendor — a setup allowing for optimal flexibility and supply reliability.

The custom synthesis contract can cover either the target compound or related intermediates, the customer performing in-house the last synthesis step. The latter setup is typical of several pharmaceutical companies who most often keep in-house these parts of the synthesis process described in the drug master file (DMF) for both quality and tax optimization considerations. As an example, a leading US pharmaceutical company has contracted three vendors to supply the intermediates required for one of its top selling substances, the last couple of synthesis steps being performed in the company's Puerto Rico plant. Such a setup is believed to provide for:

- Optimal efficiency — extracting the best possible price concessions from the three vendors, systematically putting these in direct competition.
- Outstanding capital efficiency — the investment in own synthesis capacity being limited to a bare minimum.
- Superior tax efficiency — performing the last synthesis steps in a tax heaven like Puerto Rico allowing to capture substantial tax concessions.

6. Key Success Factors

Expectations vested by customers in their custom chemicals vendors vary depending on the:

- End product application, itself a key determinant of:
  - Purity requirements.
  - Ultimate impact of the chemical input on the end user price structure and hence at least indirectly scope for value pricing available to the custom chemicals vendor.
  - Regulatory hurdles associated with changes in the production process or in the production site — these being the most stringent in the pharmaceutical outlet.
  - Ultimate tonnages achievable.
- Complexity of the product in terms of elements such as length of the synthesis, type of technologies involved in the production process as well as possible technical hurdles.
- Position of the product in its life cycle.

The most important considerations applied by customers in the selection of vendors include:

- *Competitive unit costs*. These are particularly critical for products in their maturity phase going for commodity applications characterized by intense price competition. Examples of such products include intermediates and actives for the agrochemical industry or for personal care applications. In contrast unit costs are of limited concern for products in their development phase and/or characterized by rich margins such as development pharmaceuticals where timely supply availability rather than price is the key.
- *Supply reliability*. Most often custom chemicals representing for the customer key inputs in view of further processing, penalties associated with supply chain disruption being almost invariably substantial.
- *Service*. The customer expects from his custom chemicals vendors the ability and willingness to meet requests, even if these go beyond what has been agreed in the original contractual arrangements. Examples of such requests may include the supply of odd lots, providing at short notice volumes going beyond what has been indicated in the rolling forecasts, maintaining a buffer stock or accept to withheld an invoice.
- *Technical capabilities*. Customers tending to select vendors on the basis of their (perceived) skills.
- *Responsiveness*. The lead time required by the vendor to respond to the customer requests be these in terms of returning calls or ramp up full-scale production.

These expectations can be translated in terms of key success factors that custom chemicals vendors have to meet to effectively compete. These include:

- Clear positioning, i.e., clearly targeting selected customer groups offering them a credible range of capabilities and services
- Impeccable operations management.

- A service-oriented organization allowing for simple and direct interfaces with the customer. Within this frame a critical element is represented by ensuring a careful alignment and involvement of the entire vendor organization to the customer needs and requirements.
- Standing power, hinging on a combination of factors such as ownership structure, financial strength, environmental situation, etc.
- Transparent communication channels — the customer expecting to be informed on all developments that may have an impact on the products he is outsourcing. These include a change in the process, a new source of raw materials, technology advances that may impact yields. Interesting to note, whilst the customer expects full transparency from his vendors, these are often treated as dispensable resources rather than as genuine business partners!

The role of size as a key success factor in custom chemicals represents a highly controversial topic. At least until recently some industry analysts have been considering size as important, several companies openly stating that sales of at least $ 500 $\times 10^6$ would be needed to continue to effectively compete. Such views were based on the assumption that through a larger size the vendor would be able to increase his standing vis-à-vis customers reducing thereby their ability to exert leverage. Similarly, size has been associated with ability to afford a larger range of resources as well as to better diversify the product portfolio, ensuring thereby more resilience against business vagaries.

Another school of thought is rather viewing size as an obstacle, size going in parallel with increasing organizational complexity with as a corollary loss of flexibility, lower responsiveness and higher fixed costs.

Empirical evidence suggests that an optimum probably exists in terms of size in custom synthesis. At least in Western countries this optimum is in the range of $ 100 to 200 $ $\times 10^6$. Below such as turnover vendors are typically hard pressed to effectively cover their fixed costs and to assemble a well diversified product portfolio. Passed the $ 200 $\times 10^6$ threshold, efficiency and responsiveness tend to decrease often nullifying possible benefits resulting from a larger scale.

7. Industry Size and Growth

No reliable data exist on the size of the custom chemicals space — estimates ranging from less than $ 10 $\times 10^9$ to more than $ 50 $\times 10^9$. This wide range reflects the extreme fragmentation and ill-defined boundaries of custom chemicals whose scope spans across all segments of the chemical industry.

Even, at the individual segment level, such as for example custom-made microbial derived biopharmaceuticals or custom-made libraries of screening compounds for the agrochemical or pharmaceutical industry, it is difficult to precisely estimate the size of the demand. Only orders of magnitude typically exist. This situation originates from the dynamics intrinsic to the custom synthesis business where:

- Transparency is limited, the type of product outsourced so as the source retained being typically kept confidential.
- Only a fraction of the customer product requirements are often outsourced to third party vendors.
- Unit prices paid to the vendor and volumes outsourced are rarely publicly available.

As a result market estimates are most often based on a number of assumptions — some extremely difficult to validate — including:

- Value of the chemical as a percent of the end product sales price. As an example a frequently applied rule of thumb is to put the value of the drug substance and of the agrochemical active at 6 – 8 % and 20 – 25 % of the end product price, respectively. The robustness of such estimates is, however, all but established.
- Share of outsourcing as a percentage of total requirements. Here too only rough estimates are available at least at the consolidated level.

Thus, given the number of hypothesis and assumptions only rough estimates can be provided. As an example the total custom biopharmaceutical market in 2004 is tentatively estimated between $ 1000 $\times 10^6$ and $ 1700 $\times 10^6$ (Arthur D. Little estimates) (High Tech Business Decisions consulting). This broad range reflects at least partly different definitions, the lower estimate

excluding products supplied under the frame of licensing agreements.

Similarly, the size of the custom chemical demand for applications such as detergent components, e.g., optical brighteners or bleaching agents, is difficult to estimate as some supply agreements call for the customer to provide for the raw materials. This situation is in sharp contrast with constructs applied by other companies relying on the vendor to source on his own the required inputs — clearly providing a major source of distortion!

Growth in custom chemicals is equally difficult to precisely assess, growth also often differing depending when measured in volume or value terms. Overall growth of custom chemicals is projected to outpace the corresponding chemical demand and this across most segments. This situation reflects the trend towards increasing outsourcing of chemical operations noted among several end user groups. The drivers behind this trend are multiple including, as explained in more detail in Chapter 2:

- Strategies of end users to focus on key competences and activities truly contributing to create value.
- Attempts to reduce in own capacity and to avoid inflating the fixed cost base.
- Emergence of reliable set of suppliers.

These factors are expected to favor a steady growth of outsourcing. However, it is important to recognize that an upper boundary is unlikely to be exceeded in terms of share of outsourcing as it is not credible to expect that all users will ever entirely embrace a virtual model of chemical operations where they would totally rely on third party vendors!

Also, whilst the growth outlook for custom chemicals is positive in volume terms, unit prices tend to be increasingly under pressure. This is reflecting:

- Leverage applied by customers to their vendors.
- Intense competition between vendors — by and large the custom chemicals space being characterized by an overcapacity situation.
- Inroads of new sets of players including Chinese and Indian vendors offering their services at highly competitive rates, reflecting both lower labor costs and less sophisticated pricing policies, sometimes failing to take into account the cost of capital!

As a result it is common for unit prices associated with the supply of a given custom chemical to decline of a few percentage points every year. This unit price erosion is at least partly offsetting volume growth, resulting for some segments of the custom chemicals space in flat or below GDP growth rates.

8. Concluding Remarks

Custom synthesis has more to do with a service industry than the supply of products. Probably it is the German language and terminology designating custom synthesis as "Lohnsynthese", namely synthesis-at-a-fee that best captures the essence of the business. The vendor is compensated for his molecule building activities performed at the request of a specific customer having retained his services.

Custom synthesis as a business is characterized by highly distinctive dynamics compared to the supply of standard chemicals. These distinctive traits include:

- A substantial interdependence between the vendor and the customer. The vendor is entirely dependent on the customer for each specific product, this dependence link being typically lesser for the customer.
- An extreme fragmentation reflecting the multitude of products, customers, as well as the range of contractual relations existing between the customer and the vendor. This fragmentation provides rich opportunities for small players to successfully compete in the custom chemical space as the scope and need for economies of scale is all but certain.
- Typical service dynamics, the vendor being retained to provide his services on the basis of his capabilities such as R& D or reactor volumes in view of eventually supplying a chemical related output, tailor-made at the specific request of a given customer.

According to some observers custom chemicals represent a highly attractive space, given:

- Predictions of continuous growth fuelled by expanding outsourcing of molecule building activities by end users such as specialty chemicals companies as these focus on areas of

core competence and strive to reduce capex outlays, rather relying on third party vendors.
- Expectations of improving profitability for custom chemicals vendors driven by accelerating supply structure consolidation as small players are squeezed out of the market and customers increasingly rely on their custom vendors for critical inputs — providing thereby scope for value pricing. This would obviously result in lower rivalry between vendors, that combined with lesser customer bargaining power should ultimately translate in expanded profit margins.

These views are strongly challenged by other analysts pointing:

- The limited scope for economies of scale among vendors — failing to support the thesis calling for an overdue supply structure consolidation. Another element appearing to plead against this consolidation is represented by the growing inroads of Chinese and Indian suppliers suggesting that at least in some segments entry barriers are limited.
- The intrinsic disequilibrium in the customer — vendor balance of power. Within this frame the extreme dependence of the vendor on his customer cannot be overemphasized. The vendor having at his disposal very few levers to control his own fate, at least for each individual product. This dependence can be illustrated by the setbacks suffered in the early 1990s by Hickson (Castleford, UK) producing on a custom basis a detergent component for Unilever (Rotterdam, Netherlands), this product being eventually withdrawn from the market. This had far reaching implications for Hickson who saw its capacity utilization and hence revenue stream dramatically fall overnight.

Most probably reality lies in-between these extreme views. Custom synthesis can be attractive, subject to clearly understanding its dynamics and managing these activities accordingly. Also, most importantly, it is critical for vendors already active in this field or planning to enter it to vest realistic expectations on the ultimate profit and growth potential achievable.

The human immunodeficiency virus (HIV) has been identified as the etiologic agent causing the Acquired Immuno Deficiency Syndrome (AIDS). The currently used agents for the treatment of HIV infection mainly target two important viral enzymes or inhibit viral fusion. The nucleoside analogs prematurely terminate the transcription of the viral RNA into dsDNA by reverse transcriptase. The non-nucleoside inhibitors constitute the second class of reverse transcriptase inhibitors. HIV protease, a homodimeric enzyme, is susceptible to inhibition by peptide-like structures. The process of entry of the HIV virus into the target cell can be divided into an attachment step and a fusion step. While only one inhibitor of the fusion step, Enfuvirtide, has entered the market up to now, several small-molecule inhibitors are currently in advanced development. Important efforts are being directed at the development of vaccines that can protect against HIV infection. Continued efforts are being directed at the discovery of therapies which target other essential features of the virus' life cycle, that is, the viral enzyme integrase, the viral maturation process, and the viral infectivity factor.

1. Introduction — HIV and AIDS

The human immunodeficiency virus (HIV) has been identified as the etiologic agent causing the *Acquired ImmunoDeficiency Syndrome* (AIDS) [1, 2]. In the last twenty-five years, AIDS has become the world's most deadly infectious disease, and is the leading cause of death worldwide among those ages 15–59 (20 million deaths since the pandemic began according to a recent World Health Organization report) [3]. It is estimated that 40 million people worldwide are currently suffering from HIV/AIDS infection [4]. About two-thirds of all people living with HIV are in sub-Saharan Africa, as are more than three-quarters of all women living with HIV [4]. The magnitude of this tragedy warrants the unprecedented search for treatment of this deadly disease.

1.1. HIV Cytopathogenesis and AIDS

There are two distinct types of human retroviruses, HIV-1 and HIV-2. Both are members of the lentivirus group of retroviruses. Differences between HIV-1 and HIV-2 are well documented in terms of transmissibility, pathogenesis, and geographic distribution [5, 6]. HIV-1 is widespread across the world and dominates the

10.1002/14356007.c13_c01.pub2

pandemic while HIV-2 only occurs at high rates in Western Africa. While the HIV-1 subtype B strains predominate in Europe and the Americas, other HIV-1 subtypes (such as A, C, and D) constitute the majority in Africa [7]. Other subtypes and recombinant forms also increasingly circulate in different parts of the world (such as clade H and CRF02_AG in Central Africa, CRF01_AE in South East Asia [7] and CRF12_BF in South America [8, 9]. Monitoring the antiviral activity of existing and novel anti-HIV agents against this broad and evolving genomic diversity is an aspect of today's therapy.

AIDS results from infection of components of the human immune system by HIV. The consequence of this event is a severe immunosuppression resulting from destruction of CD4-positive T-helper lymphocytes and macrophages (see also → Blood, → Blood, Chap. 2.1.3). HIV can be chronically expressed at a low level for extended periods (average about 10 years from initial infection to clinical disease). During this prolonged disease-free phase, the CD4 cell-count slowly decreases to a level below which the immune system is no longer effective against opportunistic pathogens, resulting in the emergence of multiple infections, tumors, and, ultimately, death [10–12].

1.2. Virus Life Cycle

The HIV-1 genome consists of ten open reading frames encoding structural, regulatory and accessory proteins (Table 1, Fig. 1) [13–15]. Products of the *gag* gene form the major components of the virion core. The *pol* gene encodes all important enzymes required for DNA synthesis and integration, and processing of viral polyproteins. The *env* gene product is a structural glycoprotein that is important in AIDS pathogenesis. Regulatory proteins (*tat*, *rev* gene products, as well as others shown in Table 1) are required for control of the viral replication cycle. Finally, accessory gene products (*vpu*, *vif*) perform important functions related to virion maturation, release and infectivity.

HIV infection is mediated by the sequential interaction of the *gp*120 glycoprotein on the surface of the virus with the cellular receptor molecule, the CD4 glycoprotein, and then a coreceptor, which are usually the chemokine receptor molecules CCR5 and CXCR4 (Fig. 1). These interactions lead to the activation of the fusogenic transmembrane viral glycoprotein gp41. Following fusion with the host cell membrane and uncoating of the viral particle, viral single-stranded RNA is transcribed into double-stranded DNA (dsDNA) by the reverse transcriptase (RT) enzyme. After transport into the cell nucleus, integration of viral dsDNA by the integrase (IN) enzyme into the cellular chromosomal DNA generates *provirus*. The virus has now permanently infected the cell. Following a latency period, expression of the provirus leads to virus replication. Viral messenger RNAs are spliced and transported into the cytoplasm where viral protein synthesis occurs. In the final stages of replication, *gag* and *gag-pol* precursor proteins and two molecules of viral RNA assemble with envelope protein to form an immature virion. The autocatalytically released HIV protease then cleaves the remaining protein precursors to form a new, mature and infectious viral particle that is released from the cell.

Table 1. HIV-gene functions

Genes	Functions
Structural	
gag	matrix, virion maturation and stability, capsid, virus particle maturation and release
pol	proteolysis of viral polyprotein nucleic acid replication and integration
env	external envelope, receptor binding, virion infectivity
Regulatory	
tat	transcription transactivator increasing viral gene expression
rev	rna binding protein, regulator of protein expression
tev/tnv	undefined
nef	negative factor, virus propagation
vpr	early regulatory protein
Accessory	
vif	viral infectivity factor, cell-free virus transmission, *env* processing
vpu	virus maturation/release

1.3. Current Targets of Drug Intervention

Intense studies on the replication cycle of the virus continue to provide opportunities for therapeutic intervention [16]. So far the currently used agents for the treatment of HIV infection mainly target two important viral enzymes (the

Figure 1. HIV virus life cycle

early stage reverse transcriptase and the later stage protease), or inhibit viral fusion.

To infect a cell, the HIV virus must first fuse its membrane with the cellular membrane. This process is mediated by the viral envelope glycoprotein on the surface of the virus, which is composed of trimers of noncovalently associated heterodimers of gp120 and gp41. Following interaction of gp120 with the cellular receptors (CD4 and CCR5/CXCR4), the N-terminal hydrophobic fusion peptide of gp41 inserts into the cellular membrane and triggers extensive conformational changes resulting in the coming together of the viral and cellular membranes and ultimately fusion. The discovery that inhibition of this process prevented infection led to the successful development of a peptidic inhibitor of fusion.

Reverse transcriptase is unique to retroviruses and since no analogous enzyme activity is present in normal mammalian cells, inhibitors of this enzyme were viewed as particularly attractive therapeutics, with the potential for a large margin of safety [17]. Reverse transcriptase transforms the single-stranded RNA virus genome into dsDNA, prior to integration into the host genome. Firstly, it transcribes a strand of DNA that is complementary to the viral RNA. Secondly, as this process is occurring, reverse transcriptage degrades the original RNA strand (using the ribonuclease H domain of reverse transcriptase), leaving a single stranded DNA that in turns serves as template for the synthesis of a complementary [18] DNA strand, resulting in dsDNA. The first licensed anti-HIV inhibitors were targeted at reverse transcriptase and since then several new compounds with improved properties have increased the list.

HIV protease, another essential protein in the virus life cycle, processes the *gag* and *gag-pol* gene products. Cleavage of these polyproteins by the protease at specific sites generates the proteins and enzymes required for viral maturation [19, 20]. The discovery that inhibition of the protease resulted in the production of non-infectious, immature virions [21, 22] led to the development of several inhibitors of this enzyme [23–26].

2. Reverse Transcriptase Inhibitors

2.1. Introduction

Two classes of reverse transcriptase inhibitors are used in clinical practice. The first identified were the *nucleoside analogs* (commonly referred to as NRTIs), which constitute the backbone of first line therapeutic intervention [27] and most subsequent lines. After conversion to their triphosphates, which are the pharmacologically active species within cells, the nucleoside analogs mimic the natural substrates of the en-

zyme. However, since the analogs lack the 3′-OH group necessary for DNA chain elongation, they prematurely terminate the transcription of the viral RNA into dsDNA. They may also act as competitive inhibitors with respect to the natural nucleoside substrates. More recently tenofovir, a *nucleotide* reverse transcriptase inhibitor, was added to the list of approved chain terminators. These inhibitors typically still have some affinity for endogenous DNA polymerase enzymes, which can lead to limiting side effects.

The *non-nucleoside inhibitors* (commonly referred to as NNRTIs) constitute the second class of reverse transcriptase inhibitors. In contrast to the nucleoside analogs, these drugs bind to a lipophilic site of the reverse transcriptase located close to the active site and reduce the conformational flexibility of the enzyme. Non-nucleoside inhibitors are characterized by extremely high selectivity for reverse transcriptase, and are ineffective even against the closely related HIV-2 reverse transcriptase. These drugs are used in combination with the various nucleoside reverse transcriptase inhibitors in multiple therapy regimens. The use of NNRTIs is however limited by extensive cross-resistance within this class.

2.2. Nucleoside Analogs

Zidovudine [*30516-87-1*], 3′-azido-3′-deoxythymidine, AZT, $C_{10}H_{13}N_5O_4$, M_r 267.2, *mp* 116–118 °C [28, 29], was the first nucleoside inhibitor approved for use in the treatment of AIDS in 1987, and still constitutes an important component of the backbone of combination regimens that include other nucleoside reverse transcriptase inhibitors, nonnucleoside reverse transcriptase inhibitors and protease inhibitors.

Synthesis [28, 29] (see scheme on top of the next column):

Trade names (zidovudine): Retrovir® (GlaxoSmithKline), Combivir® (coformulation tablet of zidovudine and lamivudine, GlaxoSmithKline). Trizivir® (coformulation tablet of zidovudine, lamivudine and abacavir sulfate, GlaxoSmithKline)

Didanosine [*69655-05-6*], 2′,3′-dideoxyinosine, ddI, $C_{10}H_{12}N_4O_3$, M_r 236.2, *mp* 177–180 °C (several values in the literature).

Synthesis [30]:

Trade name: Videx® (Bristol-Myers Squibb Co).

Zalcitabine [*7481-89-2*], 2′,3′-dideoxycytidine, ddC, $C_9H_{13}N_3O_3$, M_r 211.2, *mp* 215–217 °C. ddC is no longer a recommended component of therapy and has been withdrawn in some countries.

Synthesis [31]:

Trade name: Hivid® (Hoffmann-LaRoche).

Stavudine [*3056-17-5*], 2′,3′-didehydro-3′-deoxythymidine, d4T, $C_{10}H_{12}N_2O_4$, M_r 224.2, *mp* 165–166 °C.

Synthesis [32]:

Trade name: Zerit® (Bristol-Myers Squibb Co).

Lamivudine [*134678-17-4*], (2*R*,5*S*)-4-amino-1-[2-(hydroxymethyl)-1,3-oxathiolan-5-yl]-2(1*H*)-pyrimidinone, 3TC, $C_8H_{11}N_3O_3S$, M_r 229.3, *mp* 158–160 °C.

Synthesis [33, 34]:

Trade names: Epivir® (GlaxoSmithKline), Combivir® (coformulation tablet of lamivudine and zidovudine, GlaxoSmithKline). Trizivir® (coformulation tablet of zidovudine, lamivudine and abacavir sulfate, GlaxoSmithKline). Epzicom™, Kivexa™ (coformulation tablet of lamivudine and abacavir sulfate, GlaxoSmithKline).

Abacavir [*136470-78-5*], (1*S*,4*R*)-4-[2-amino-6-(cyclopropylamino)-9*H*-purin-9-yl]-2-cyclopentene-1-methanol, $C_{14}H_{18}N_6O$, M_r 286.3, foam; abacavir sulfate [*188062-50-2*], (1*S*,4*R*)-4-[2-amino-6-(cyclopropylamino)-9*H*-purin-9-yl]-2-cyclopentene-1-methanol, sulfate salt (2:1), $(C_{14}H_{18}N_6O)_2H_2SO_4$, M_r 670.76, *mp* 224–225 °C.

Synthesis [35, 36]:

Trade name (abacavir sulfate): Ziagen® (GlaxoSmithKline). Trizivir® (coformulation tablet of zidovudine, lamivudine and abacavir sulfate, GlaxoSmithKline). Epzicom™, Kivexa™ (coformulation tablet of lamivudine and abacavir sulfate, GlaxoSmithKline).

Emtricitabine [*143491-57-0*], 4-amino-5-fluoro-1-[(2*R*,5*S*)-2-(hydroxymethyl)-1,3-oxathiolan-5-yl]pyrimidin-2-(1*H*)-one, FTC; $C_8H_{10}FN_3O_3S$, M_r 247.24, *mp* 166°C (form II) [37].

Synthesis [38, 39]:

Emtricitabine (Emtriva)

Trade name (emtricitabine): Emtriva® (Gilead Sciences Inc.). Truvada® (co-formulation tablet of emtricitabine and tenofovir disoproxyl fumarate) (Gilead Sciences Inc.)

2.3. Nucleotide Analogs

Tenofovir [*147127-20-6*], [[(1R)-2-(6-amino-9H-purin-9-yl)-1-methylethoxy]methyl]-phosphonic acid; $C_9H_{14}N_5O_4P$ M_r 287.21.

Tenofovir disoproxil fumarate [*202138-50-9*] is a prodrug of tenofovir. Its chemical name is bis{[(isopropoxycarbonyl)oxy]methyl}{[(1R)-2-(6-amino-9H-purin-9-yl)-1-methylethoxy]methyl}phosphonate;fumarate (1:1), $C_{19}H_{30}N_5O_{10}P{\cdot}C_4H_4O_4$ M_r 635.52, *mp* 114.2–114.6°C [40].

Synthesis [40]:

Tenofovir disoproxil fumarate (Viread)

Trade name (tenofovir disoproxil fumarate): Viread® (Gilead Sciences Inc.) Truvada® (co-formulation tablet of emtricitabine and tenofovir disoproxil fumarate) (Gilead Sciences Inc.).

2.4. Non-Nucleoside Analogs

Nevirapine [*129618-40-2*], 11-cyclopropyl-5,11-dihydro-4-methyl-6*H*-dipyrido[3,2-b:2′,3′-e][1,4]diazepin-6-one, $C_{15}H_{14}N_4O$, M_r 266.3, *mp* 247–249 °C, is a non-competitive inhibitor of HIV-1 reverse transcriptase, and was the first of the non-nucleoside reverse transcriptase inhibitor class to receive approval for use in the treatment of AIDS in 1996.

Synthesis [41]:

Nevirapine (Viramune)

Trade name: Viramune® (Boehringer Ingelheim).

Delavirdine [*136817-59-9*], 1-[3-[(1-methylethyl)amino]-2-pyridinyl]-4-[[5-[(methylsulfonyl)amino]-1*H*-indol-2-yl]carbonyl]piperazine, $C_{22}H_{28}N_6O_3S$, M_r 456.56, *mp* 226–228 °C; delavirdine methanesulfonate (mesylate) [*147221-93-0*] $C_{22}H_{28}N_6O_3S \cdot CH_4O_3S$, M_r 552.68, *mp* 220–222 °C.

Synthesis [42, 43]:

Delavirdine (Rescriptor)

Trade name (delavirdine mesylate): Rescriptor® (Pfizer, registered trademark of Pharmacia & Upjohn Co).

Efavirenz [*154598-52-4*], (4*S*)-6-chloro-4-(cyclopropylethynyl)-1,4-dihydro-4-(trifluoromethyl)-2*H*-3,1-benzoxazin-2-one, $C_{14}H_9ClF_3NO_2$, M_r 315.7, *mp* 139–141 °C.

Synthesis [44]:

Trade name (efavirenz): Sustiva™ (Bristol-Myers Squibb Co), Stocrin® (Merck & Co.).

2.5. Compounds in Development

Several additional nucleoside and non-nucleoside reverse transcriptase inhibitors are currently in various stages of clinical development. In general, these drug candidates attempt to improve on the various limitations associated with the currently used therapies. Emphasis is on safer and more convenient dosages as well as on the development of new agents with broader antiviral profiles against reverse transcriptase mutations associated with reduced susceptibility to currently approved NRTIs and NNRTIs.

Among the NRTIs in advanced stages of development, one can list: Elvucitabine (L-D4FC, ACH-126443) [*181785-84-2*] by Achillion Pharmaceuticals [45], Dexelvucitibine (D-d4FC, DPC-817) [*134379-77-4*] by Pharmasset [46], Racivir (racemic FTC) [*143491-54-7*] by Pharmasset [47], and AVX-754 (Apricitabine SPD-754, (−)-dOTC) [*160707-69-7*] by Shire/Avexa Limited [48].

Dexelvucitibine

Elvucitabine

SPD-754

Racivir (racemic FTC)

Among the NNRTIs in advanced stages of development, one can list: Etravirine (TMC-125, R-165335) [*269055-15-4*] [49] and

rilpivirine (TMC-278, R-278474) [*500287-72-9*] by Tibotec-Virco/Johnson& Johnson [50], capravirine (S-1153, AG-1549) [*178979-85-6*] by Shionogi [51], GW-5634 (GW-695634) [*457635-64-2*] a pro-drug of GW-8248 by GlaxoSmithKline [52], and BILR 355 BS [*380378-81-4*] by Boehringer Ingelheim [53, 54]. Capravirine and GW-5634 have recently being discontinued.

3. Protease Inhibitors

3.1. Introduction

Being a member of the aspartyl protease class of enzymes [26, 55], HIV protease, a homodimeric enzyme, is susceptible to inhibition by peptide-like structures incorporating various isosteres that mimic the transition state for the hydrolysis of an amide bond (Fig. 2) [23–25].

Figure 2. Protease inhibitors mimic the transition state of hydrolysis of an amide bond

Among them, hydroxyethylamine and hydroxyethylene isosteres have led to potent inhibitors of the enzyme. Despite their peptidic character (often resulting in low oral bioavailability and rapid excretion), high molecular masses (575–750) and structural complexities, these classes of compounds effectively reduce viral load in infected patients and provide physicians with additional tools for combating the deadly disease. In 2005, a non-peptidic protease inhibitor (tipranavir, Aptivus®) was approved bringing to nine the number of HIV protease inhibitors on the market. Nowadays, most protease inhibitors are often co-administered with low-dose ritonavir (another HIV protease inhibitor also inhibiting the metabolic CYP 3A4) in order to improve their pharmacokinetic properties and to lower dosage [56, 57].

3.2. Hydroxyethylamine Isosteres

Saquinavir [*127779-20-8*], [3*S*-[2[1*R**(*R**), 2*S**],3 α, 4a β, 8a β]]-N^1[3-[3-[[(1,1-dimethylethyl)amino]carbonyl]octahydro-2(1*H*)-isoquinolinyl]-2-hydroxy-1-(phenylmethyl)propyl]-2-[(2-quinolinylcarbonyl)amino]butanediamide; free base, $C_{38}H_{50}N_6O_5$, M_r 670.85, $[\alpha]_D^{20}$ −55.9 ° (c = 0.5, MeOH); monomethanesulfonate (mesylate) [*149845-06-7*], $C_{38}H_{50}N_6O_5 \cdot CH_4O_3S$, M_r 766.95.

Saquinavir was the first peptidomimetic-based HIV protease inhibitor to be approved in the United States (1995) and Europe (1996) [58–60]. A new soft gel formulation (Fortovase®) was launched in the United States (1997) and provides improved bioavailability.

Synthesis [61]:

Trade names: Invirase® (saquinavir mesylate, Ro 318959, Hoffmann-La Roche, Switzerland, must be co-administered with ritonavir to improve plasma levels). Fortovase® (soft gel formulation, Ro 318959 003, Hoffmann-La Roche, Switzerland).

Nelfinavir [*159989-64-7*],[3*S*-[2(2*S**,3*S**), 3 α 4a β, 8a β]]-*N*-(1,1-dimethylethyl)decahydro-2-[2-hydroxy-3-[(3-hydroxy-2-methylbenzoyl)amino]-4-(phenylthio)butyl]-3-isoquinolinecarboxamide; free base $C_{32}H_{45}N_3O_4S$, M_r 567.80; monomethanesulfonate (mesylate) [*159989-65-8*], $C_{32}H_{45}N_3O_4S \cdot CH_4O_3S$.

Synthesis [62, 63]:

Nelfinavir mesylate (Viracept)

(a: [64], b: [65])

Trade names (nelfinavir mesylate): Viracept® (PfizerAgouron, Japan Tobacco; Hoffmann-La Roche).

Amprenavir [*161814-49-9*], (3*S*)-tetrahydro-3-furyl N-[(1*S*,2*R*)-3-(4-amino-N-isobutylbenzenesulfonamido)-1-benzyl-2-hydroxypropyl]carbamate; free base $C_{25}H_{35}N_3O_6S$, M_r 505.64.

Synthesis [66]:

Amprenavir (Agenerase)

Trade name: Agenerase® (GlaxoSmithKline; licensed from Vertex Pharmaceuticals Inc), Prozei® (Kissei Pharmaceutical, Japan; licensed from Vertex Pharmaceuticals Inc.).

Fosamprenavir calcium [*226700-81-8*], (3*S*)-tetrahydrofuran-3-yl (1*S*,2*R*))-3-[[(4-aminophenyl)sulfonyl](isobutyl)amino]-1-benzyl-2-(phosphonooxy)propylcarbamate monocalcium salt; $C_{25}H_{34}CaN_3O_9PS$, M_r 623.7, *mp* 282–284 °C is a prodrug of amprenavir that was approved in 2003 for use in combination with

reverse transcriptase nucleoside / nucleotide analogs without or with ritonavir.

Synthesis [67, 68]:

Fosamprenavir calcium (Lexiva)

Trade name: Lexiva®, Telzir™ (GlaxoSmithKline; licensed from Vertex Pharmaceuticals Inc., USA).

3.3. Hydroxyethylene Isosteres

Ritonavir [*155213-67-5*], [5*S*-(5*R**,8*R**,10*R**,11*R**)]-10-hydroxy-2-methyl-5-(1-methylethyl)-1-[2-(1-methylethyl)-4-thiazolyl]-3,6-dioxo-8,11-bis(phenylmethyl)-2,4,7,12-tetraazatridecan-13-oic acid 5-thiazolylmethyl ester; free base $C_{37}H_{48}N_6O_5S_2$, M_r 720.96.

Ritonavir is a peptidomimetic inhibitor of HIV-1 and HIV-2 proteases that was approved in 1996 for use in combination with reverse transcriptase nucleoside analogs. It reversibly and potently inhibits cytochrome P450 enzymes, thus inhibiting not only its own metabolism, but also inhibiting the metabolism of other drugs to which it is combined [69]. For this reason, ritonavir has found utility as a boosting agent when administered at low dose in combination with certain anti-HIV agents to improve their pharmacokinetic properties (such as exposure and half-life) [56, 57].

Synthesis [70–72] (see next page)

Indinavir [*150378-17-9*], [1(1*S*,2*R*),5(*S*)]-2,3,5-trideoxy-*N*-(2,3-dihydro-2-hydroxy-1*H*-inden-1-yl)-5-[2-[[(1,1-dimethylethyl)amino]carbonyl]-4-(3-pyridinylmethyl)-1-piperazinyl]-2-(phenylmethyl)-D-erythropentonamide; free base $C_{36}H_{47}N_5O_4$, M_r 613.80, *mp* 153–154 °C (anhydrous form), $[\alpha]_D^{20}$ + 24.1 ° (*c* = 0.0133, $CHCl_3$); sulfate [*157810-81-6*], $C_{36}H_{47}N_5O_4 \cdot H_2SO_4$, M_r 711.88, crystals from absolute ethanol, softens at 135 °C, *mp* 150–153 °C (decomp.).

Synthesis [73]:

Trade name: Norvir (Abbott Laboratories).

Indinavir sulfate (Crixivan)

Trade name (indinavir sulfate): Crixivan® (Merck & Co. USA).

Lopinavir [*192725-17-0*], [1*S*-[1*R**,(*R**), 3*R**, 4*R**]]-N-[4[[(2,6-dimethylphenoxy)acetyl]amino]-3-hydroxy-5-phenyl-1-(phenylmethyl)pentyl]tetrahydro-alpha-(1-methylethyl)-2-oxo-1(2H)-pyrimidineacetamide; $C_{37}H_{48}N_4O_5$, M_r 628.80, crystals from ethyl acetate/heptane *mp* 124–127 °C;), $[\alpha]_D^{22}$ −22.85° (*c* = 0.4, CH_3OH). Lopinavir is a potent inhibitor of HIV-1 protease whose pharmacokinetic parameters were found to be greatly enhanced by low dose ritonavir. It is indicated for HIV therapy only as a combination with ritonavir.

Synthesis [74] (see right column):

Trade name (lopinavir/ritonavir): Kaletra® (Abbott Laboratories, a 4:1 coformulation tablet or oral solution of lopinavir and ritonavir as a boosting agent).

Atazanavir [*198904-31-3*], (3*S*,8*S*,9*S*,12*S*)-3,12-bis(1,1-dimethylethyl)-8-hydroxy-4,11-dioxo-9-(phenylmethyl)-6-[[4-(2-pyridinyl)phenyl]methyl]-2,5,6,10,13-pentaazatetradecanedioic acid dimethyl ester; free base $C_{38}H_{52}N_6O_7$, M_r 704.9; bisulfate [*229975-97-7*], $C_{38}H_{52}N_6O_7 \cdot H_2SO_4$, M_r 802.9, $[\alpha]_D^{22}$ −46.1 (*c* = 1, 1:1 MeOH/H_2O, pH = 2.6) [75], crystals from acetone *mp* 198–199 °C (decomp.) [76]. Atazanavir is an azapeptide inhibitor of HIV protease. Atazanavir bisulfate is co-administered with low-dose ritonavir in treatment-experienced patients and without ritonavir in treatment-naive patients.

Lopinavir

Synthesis [75]:

Atazanavir bisulfate (Reyataz)

Trade name (atazanavir sulfate): Reyataz® (Bristol-Myers Squibb Co, licensed from Novartis)

3.4. Non-Peptidic Inhibitors

Tipranavir [*174484-41-4*], *N*-(3-{(1*R*)-1-[(6*R*)- 4-hydroxy-2-oxo-6-(2-phenylethyl)-6-propyl-5,6-dihydro-2*H*-pyran-3-yl]propyl}phenyl)-5-(trifluoromethyl)pyridine-2-sulfonamide; $C_{31}H_{33}F_3N_2O_5S$, M_r 602.7; crystals from ethyl acetate / heptane *mp* 86-89 °C [77] $[\alpha]_D^{22}$ +22 ° (c = 0.96, CH_3OH) [78]. Tipranavir has been approved in 2005 and is one of the latest protease inhibitor to enter the market. It must be administered with low-dose ritonavir.

Synthesis [77]: see next page.

3.5. Compounds in Development

Several second-generation HIV protease inhibitors are presently being evaluated in the clinic (Fig. 3). Among the PIs in advanced stages of development, one can list: Darunavir (TMC114) [*206361-99-1*] by Tibotec-Virco/Johnson& Johnson (approved in 2006 as Prezista™) [79], Brecanavir (GW640385, GW0385, VX-385 another hydroxyethylamine nonpeptidic inhibitor) [*313682-08-5*] by GlaxoSmithKline [80], AG-001859 (an hydroxyethylene isostere containing the unnatural amino acid allophenylnorstatine) [*478410-84-3*] by Pfizer [81, 82].

Trade name (tipranavir): Aptivus® (Boehringer Ingelheim, licensed from Pharmacia & Upjohn Co., must be co-administered with low dose ritonavir as a boosting agent).

Synthesis [77] :

4. Entry Inhibitors

4.1. Introduction

The process of entry of the HIV virus into the target cell is a complex, multistep event. This process is often divided into two main steps; *attachment* (whereby viral gp120 interacts with CD4 receptor and subsequently with co-receptors CCR5 or CXCR4), and *fusion* (whereby trimeric viral gp41 undergoes conformational changes to initiate membrane fusion). Intensive studies are conducted to identify inhibitors at each of these steps [83, 84]. So far, only one inhibitor of the fusion step has entered the market.

4.2. Fusion Inbihitor

The folding onto each other of the N- and C-peptide regions of gp41 trimer leads to a six-helix bundle which is at the center of the conformational change initiating membrane fusion. Synthetic peptides derived from the C-peptide region have been shown to be potent inhibitors of HIV-1 replication by interfering with the formation of the fusogenic six-helix bundle. They provided the impetus for the discovery of the only fusion inhibitor currently approved so far [85, 86].

Enfuvirtide [*159519-65-0*], N-acetyl-L-tyrosyl-L-threonyl-L-seryl-L-leucyl-L-isoleucyl-L-histidyl-L-seryl-L-leucyl-L-isoleucyl-L-α-glutamyl-L-α-glutamyl-L-seryl-L-glutaminyl-L-asparaginyl-L-glutaminyl-L-glutaminyl-L-α-glutamyl-L-lysyl-L-asparaginyl-L-α-glutamyl-L-glutaminyl-L-α-glutamyl-L-leucyl-L-leucyl-L-α-glutamyl-L-leucyl-L-α-aspartyl-L-lysyl-L-tryptophyl-L-alanyl-L-seryl-L-leucyl-L-tryptophyl-L-asparaginyl-L-tryptophyl-L-phenylalaninamide, T-20; $C_{204}H_{301}N_{51}O_{64}$, M_r 4491.56.

Enfuvirtide was the first fusion inhibitor approved for the treatment of HIV infection in 2003. It is a 36-mer oligopeptide that must be reconstituted in water and self-administered subcutaneously by the patient.

Synthesis [87, 88]: see next page.

4.3. Compounds in Development

Several small-molecule inhibitors, targeting the different steps of the entry process, are currently in advanced development. Among this growing class, one can list:

BMS-488043 (a small molecule blocking viral entry by binding to the viral gp120 and preventing interaction with the CD4 receptor) [*452296-83-2*] by Bristol-Myers Squibb Co [89], Maraviroc (UK-427,857, a CCR5 co-receptor antagonist) [*376348-65-1*] by Pfizer [90], Aplaviroc (GW873140, ONO-4128, AK-602, a CCR5 co-receptor antagonist) [*461443-59-4*] by ONO Pharmaceuticals licensed to GSK [91], Vicriviroc (SCH-D, SCH-417690, a CCR5 co-receptor antagonist) [*306296-47-9*] by Schering-Plough [92] and BlockAide/CR (a peptide-based drug that inhibits the interaction of the V3 loop with host cell lipids) by ADVENTRX Pharm./Synteract Inc. Aplaviroc has recently been discountinued.

5. Emerging Concepts in AIDS Therapy

Despite evidence that the immune response cannot destroy HIV, it is believed that boosting of the body's defense mechanism in preparation for the viral attack, may succeed in containing the virus. Important efforts are being directed at the development of vaccines that can protect against HIV

Trade name (enfuvirtide): Fuzeon™ (Roche Laboratories Inc., licensed from Trimeris Inc.).

infection [93–95]. Current strategies include the search for agents that stimulate humoral cellular immune responses by targeting the *env* surface glycoprotein of HIV. On another front, the use of live-attenuated HIV to elicit an immune response is being hampered by potential reversion to pathogenic strains. The lack of understanding of the immune correlates of protection makes vaccine development highly complex and challenging. Coupled to the high variability of the HIV virus, it is unlikely that suitable vaccines for use in humans will become available in the near future [96–98].

Most efforts to treat HIV infection are concentrated on the development of drugs, which arrest the replication cycle of the virus. Most utilized at the present time, reverse transcriptase and protease inhibitors which have long been the major focus of the search for antivirals. Due to the emergence of drug resis-

tance [99], drug failure, and side effects associated with the use of such agents, continued efforts are being directed at the discovery of novel therapies, which target other essential features of the virus' life cycle. These include (i) the viral enzyme integrase which has long been a focus of attention and is now generating promising inhibitors [100–103], (ii) the viral maturation process [104], and more recently (iii) the viral infectivity factor (Vif) [105, 106]. In addition, immune-based approaches such as monoclonal antibodies and immune reconstitution [107–110], inhibitors of cytokine-mediated virus activation [111, 112], soluble CD4 [113] and antisense oligonucleotides [114–116] are all being actively explored.

While major advances in treatment based on combination therapies with reverse transcriptase and protease inhibitors [16] have been made, a definitive cure to the disease remains elusive at this time. A most sought vaccine combined with easier access to drugs in the developing world and strong preventive measures remain the only true hope for arresting this global epidemic.

6. Acknowledgement

We are grateful to Helene Gagnon and Georges Medawar for help with literature searches.

Notation

(Dimensions given in terms of mass, M, length, L, time, T, and temperature, θ)

A	arithmetic mean, acceleration (L/T^2)
A	area (L_2)
A_i	area of inlet nozzle of hydrocyclone (L_2)
A_{1n}	parameter dependent on the flow behavior index
C	volume fraction of solids in suspension
C_D	drag coefficient
C'_n	parameter dependant on the flow behavior index
C_{y50}	dimensionless cyclone number
D	pipe diameter (L)
D_c	hydrocyclone diameter (L)
D_i	inlet diameter of hydrocyclone (L)
D_o	overflow pipe diameter of hydrocyclone (L)
D_u	underflow pipe diameter of hydrocyclone (L)
E_p	partial efficiency
E_t	total efficiency
E'_t	reduced total efficiency
Eu	Euler number
f	fanning friction factor
f_{pv}	purely viscous fanning friction factor
$f(x)$	frequency
$F_c(x)$	cumulative percentage oversize of separated solids
F_D	drag force (MLT^{-2})
$F_f(x)$	cumulative percentage oversize of non-separated solids
$F(x)$	cumulative percentage oversize of feed solids

© 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.c13_c02.pub2

g	acceleration due to gravity (L/T^2)
$G(x)$	grade efficiency
$G'(x)$	reduced grade efficiency
H	height of liquid column or liquid head (L)
H_i	height of rectangular inlet channel of hydrocyclone (L)
$H_{25/75}$	sharpness index
k_p	empirical constant for a family of geometrically similar hydrocyclones
k_1, k_2	constants
K	constant, correlation constant of the power law
K'	fluid consistency index (MT^n/L^2)
l	vortex finder length (L)
L	hydrocyclone length (L)
L_1	length of cylindrical part of hydrocyclone (L)
m	exponent, mass (M)
M	mass flows rate of solids in suspension (M/T)
M_c	mass flows rate of separated solids (M/T)
M_f	mass flows rate of nonseparated solids (M/T)
n	exponent; slope of the curve representing the power law
n_p	empirical constant for a family of geometrically similar hydrocyclones
n'	flow behavior index
N	revolutions per minute or per second (1/T)
O	volumetric flow rate of overflow suspension (L^3/T)
P	pressure (M/LT^2)
q	volumetric flow rate per unit area (L/T)
Q	volumetric flow rate (L^3/T)
r	parameter function of a log-ln plot in the coarse region
R	radius of rotation (L)
R_{av}	average radius of rotation (L)
Re	Reynolds number
Re_p	particle Reynolds number
Re^*	Reynolds number for power-law fluids
R_f	underflow-to-throughput ratio
s	parameter function of the slope of the log-ln plot in fine size regions
Stk_{50}	Stokes number
Stk'_{50}	Stokes number including the reduced cut size
Stk^*_{50}	Stokes number for power-law fluids
$Stk^*_{50}(r)$	Stokes number for power-law fluids including the reduced cut size
t	time (T)
t_d	detention time (T)
t_s	settling time (T)
T	temperature (θ)
u	fluid-particle relative velocity (L/T)
u_t	terminal settling velocity under gravity (L/T)
U	volumetric flow rate of underflow suspension (L^3/T)
v	linear velocity, hydrocyclone characteristic velocity (L/T)
v_g	terminal settling velocity under gravity (L/T)
v_i	inlet tangential velocity (L/T)
v_o	maximum tangential velocity (L/T)
v_r	radial settling velocity (L/T)
v_t	tangential velocity (L/T)
V	volume (L^3)
w	vertical velocity at cyclone wall (1/T)
x	particle size (L)
x_a	arithmetic mean of particle size (L)
x_c	cut size (L)
x_g	geometric mean of particle distribution, mass median size of particle (L)
x_m	mode of particle size distribution
x_o	maximum particle size in sample (L)
x_r	constant function of particles size range (L)
x_0	particle size with zero centrifugal efficiency (L)
x_{50}	cut size (L)
x'_{50}	reduced cut size (L)
x_{98}	approximate particle size fully separated (L)
Z	acceleration factor
Z_i	width of rectangular inlet channel of hydrocyclone (L)
	Greek
α	constant
γ	viscosity coefficient for power-law fluids (M/LT^{2-n})
$\dot{\gamma}$	shear rate (1/T)
Δ	difference
θ	hydrocyclone cone angle
μ	liquid absolute viscosity (M/LT)
μ_o	viscosity of pure solvent (M/LT)
ρ	liquid density (M/L^3)
ρ_m	slurry density (M/L^3)
ρ_s	solids density (M/L^3)
σ	standard deviation

τ	shear stress (M/LT^2)
τ_w	shear stress at tube wall (M/LT^2)
ϕ	volume fraction of spheres in suspension
ω	angular velocity (1/T)

1. Introduction

1.1. General Remarks

Hydrocyclones have been less employed than centrifuges to develop high centrifugal forces and perform separation of solids. Although hydrocyclones were first patented more than 100 years ago, industrial use of them was practically nonexisting until the late 1940s. Hydrocyclones were early utilized in the paper and mineral industries, to become later popular in a larger number of factories from chemical, cement, and nuclear to the food, pharmaceutical, and oil industries. Although hydrocyclones continue finding new applications, the dearth of specialized literature about them is surprising. With only two known books written in English since the 1980s and some attention paid to them in the literature, there is more to learn about hydrocyclones than about other solid–liquid separation techniques.

1.2. Principle of Operation

A hydrocyclone is a sedimentation device, which employs enhanced gravity force to separate solid from a carrying liquid. This mentioned force is in fact the centrifugal field produced when a fluid suspension is pumped tangentially into a cone-cylindrical body. As a vortex is created, coarse particles move towards the wall and fines towards the axis. Flow is at first down the inner wall of the cylindrical section and the cone, as far as the stagnation point near the cone apex. There, because the opening is small, the downward primary vortex is forced to turn upwards again, thus forming the secondary vortex. Thus, at the bottom of the cone the flow splits into two streams, the underflow containing most of the coarse particles, and the overflow with most of the fines in it. The overflow pipe generally protrudes into the cylindrical body, to form what is known as the vortex finder. A diagram of a hydrocyclone is shown in Figure 1. As can be concluded, separation is based on difference in settling velocities, as in sedimentation. Thus, size, density and shape of particles play a role important in the operation.

Figure 1. Diagram of a hydrocyclone

Figure 2. Nomenclature and dimensions of hydrocyclone D_c: cyclone body diameter, D_o: overflow pipe diameter, D_i: inlet diameter, $[(4HiZ_i)/\pi]^{1/2}$ for rectangular inlet channels, l: vortex finder length, L_1: cylindrical section length, L: hydrocyclone length, θ: cone angle, D_u: underflow orifice

Typical sizes of hydrocyclones range from 10 mm to 2.5 m in diameter, capacities of sin-

gle units go from 0.1 to 7200 m^3/h, and pressure drops vary from 0.34 to 6 bar. The efficiency, reported as cut size, lies between 2 and 250 µm. The main advantages of the hydrocyclone are its simple, compact, and inexpensive construction, its ease of operation (no moving parts), its short residence time, and its manageability of sizes finer than those treated in mechanical classifiers. Some disadvantages are its high power consumption, its high wear, its inflexibility and its problem with blockage, especially in small units. Figure 2 presents typical dimensions and standard nomenclature of hydrocyclones.

2. Categories and Application

Hydrocyclones are very versatile pieces of equipment. They can be employed as thickeners, clarifiers, classifiers and even in liquid–liquid separations. A quite useful and up-to-date guide of applications and models of hydrocyclones is given in [1].

2.1. Thickening

For thickening proposes, hydrocyclones have proved to be efficient, with underflow concentration as high as 50 % obtained with some material. Thus, they can easily compete in this field with gravity thickeners, with advantages of less space requirement. The main problem in the operation, however, is the risk of blockage, but hydrocyclones with variable underflow orifice are employed to avoid this difficulty.

2.2. Clarification

When used in clarification, small diameter hydrocyclones with parallel multicyclone arrangement are preferred. Multiple cyclone units with six to several hundred hydrocyclones in parallel are available and have been successfully used.

2.3. Classification

Since the principle of operation of hydrocyclones is centrifugal, they can be used to separate solids from solids in a suspension according to particle size. Sometimes, either coarse or fine particles may be removed from the product, and hydrocyclones have performed such operations known as degritting or refining, and desliming or washing, respectively. This classifying characteristic of hydrocyclones is also employed to improve the performance of other filtration or separation equipments. The coarse and fine particles separated from hydrocyclones normally follow different paths in a processing plant, being sometimes fed into other units, to finish as a different product.

2.4. Other Applications

As hydrocyclones have been used either as thickeners or as clarifiers, they have also performed both functions in one operation. In order to do so, two or more units are connected in series. One of them functions as thickener and the others as clarifiers. A typical arrangement, which operates with the thickener at the first stage, followed by two clarification stages, and the underflow of them returned to the feed, has been widely described in [2]. Other arrangements that have also maximized the overall performance have been analyzed in [1]. The centrifugal features of hydrocyclones give them possibilities to perform separation of two immiscible liquids. Hydrocyclones have been applied in separation of oil from water, in dewatering of light oils and in producing highly concentrated samples of lighter dispersed phases. Other applications such as countercurrent washing of solids and separation of gas bubbles from feed liquids have as well been tried, giving satisfactory results.

3. Theoretical Background

3.1. Simultaneous Flow of Fluids and Solids

As hydrocyclones are usually fed with a dispersion of solids in liquid, a study of the principal characteristics of suspension is necessary. Since concentration can be vary widely in hydrocyclone operations, particle–fluid interaction, as well as proper rheology of the whole suspension,

are of the utmost importance. For a detailed description of fluid dynamics and rheology see → Fluid Mechanics.

3.1.1. Dynamics of Particles Submerged in Fluids

If a particle moves relative to the fluid in which it is suspended, the force opposing the motion is known as the drag force. Knowledge of the magnitude of this force is essential if the particle motion is to be studied. Conventionally, the drag force F_{D} is expressed as:

$$F_{\mathrm{D}} = C_{\mathrm{D}} A \frac{\rho u^2}{2} \tag{1}$$

where u is the particle–fluid relative velocity, ρ is the fluid density, A is the area of the particle projected in direction of the motion, and C_{D} is a coefficient of proportionality known as the drag coefficient. Assuming the drag force is due to the inertia of the fluid, C_{D} would be constant and dimensional analysis shows that C_{D} is generally a function of the particle Reynolds number, i.e.:

$$Re_{\mathrm{p}} = \frac{ux\rho}{\mu} \tag{2}$$

where x is the particle size and μ the medium viscosity; the form of the function depends on the regime of the flow. This relationship for rigid spherical particles is shown in Figure 3. At low Reynolds number under laminar flow conditions when viscous forces prevail, C_{D} can be determined theoretically from Navier–Stokes equations (see → Fluid Mechanics, Section 3.2) and the solution is known as Stokes' law and represented by:

$$F_{\mathrm{D}} = 3\pi\mu ux \tag{3}$$

Figure 3. Drag coefficient versus particle Reynolds number for spherical particles

This is an approximation, which gives the best results for $Re_{\mathrm{p}} \to 0$; the upper limit of its validity depends on the error that can be accepted. The usually quoted limit for the Stokes region of $\mathrm{Re_p} = 0.2$ is based on an error of about 2 % in the terminal settling velocity. Equations 1, 2 and 3 combined give another form of Stokes' law as follows:

$$C_{\mathrm{D}} = \frac{24}{Re_{\mathrm{p}}} \; (Re_{\mathrm{p}} < 0.2) \tag{4}$$

For Reynolds numbers > 1000 the flow is fully turbulent with inertial forces prevailing, and C_{D} becomes constant and equal to 0.44 (the Newton region). The region in-between $\mathrm{Re_p} = 0.2 - 1000$ is known as the transition region, and C_{D} is either described in a graph or by one or more empirical equations.

For a particle of mass m under the influence of a field of acceleration a, the equation of motion is:

$$m\left[\frac{\mathrm{d}u}{\mathrm{d}t}\right] = ma - ma\left[\frac{\rho}{\rho_{\mathrm{s}}}\right] - F_{\mathrm{D}} \tag{5}$$

where ρ_s is the density of the solids and t is the time.

In applications of hydrocyclones concerned with separation of fine particles, which are all most difficult to separate, the Reynolds numbers are low, often less than 0.2, due to the low values of x and u. Therefore, it is reasonable also that the time necessary for the particle velocity to reach values very close to the terminal settling velocity is very short and being the field of acceleration gravity, Equation (5) can be solved to give:

$$u_t = \frac{x^2\,(\rho_{\mathrm{s}} - \rho)\,g}{18\mu} \tag{6}$$

in which the acceleration due to gravity g has replaced a and u_{t} is known as the terminal settling velocity under gravity.

The radial settling velocity in a hydrocyclone v_{r} is due to the centrifugal acceleration, which is proportional to the square of the tangential velocity of the particle, and indirectly proportional to the radius of the particle position. As the tangential motion of particle is unopposed, the tangential particle velocity can be taken as equal to the tangential component of the fluid

velocity at the same point. The inclusion of the centrifugal terms in Equation (6) leads simply to:

$$v_{\mathrm{r}} = \frac{x^2\,(\rho_{\mathrm{s}}-\rho)\,R\omega^2}{18\mu} \tag{7}$$

where R is the radius of the particle position and ω is the angular velocity.

As the concentration of the suspension increases, particles get closer together and interfere with each other. If the particles are not disturbed uniformly, the overall effect is a net increase in settling velocity because the return flow caused by volume displacement predominates in particles-sparse regions. This is the well-known effect of cluster formation, which is significant only in nearly monosized suspensions. With most practical widely dispersed suspension, clusters do not survive long enough to affect the settling behavior and, as the return flow is more uniformly distributed, the settling rate steadily declines with increasing concentration. This phenomenon is referred to as hindered settling and can be theoretically approached in three different manners: as a Stokes' law correction by introduction of a multiplying factor; by adopting effective fluid properties for the suspension different from these of the pure fluid; and by determination of bed expansion with a modified version of the well know Carman–Kozeny equation. All the approaches can be shown to yield essentially identical results. Some important correlations accounting for the hindered settling effect have been reviewed in [3]. It was shown that their differences are minimal and, according to this, the Richardson and Zakii equation is an obvious choice in practice. Such relation can be expressed as:

$$\frac{u}{u_{\mathrm{t}}} = (1-C)^{4.65} \tag{8}$$

where u is the settling velocity at concentration C and u_{t} is the settling velocity of a single particle.

The relationship above applies only to free, particulate separation unaffected by coagulation or flocculation, and where all particles are of uniform density.

3.1.2. Rheology of Suspensions

The rheological properties of suspension have been studied since the beginning of the 20th century. The first research was done by Einstein[4] in his classical study of the viscosity of dilute suspensions of rigid spheres. His approach is purely hydrodynamic, and his model consists of an isolated sphere situated in a simple shear flow field in an infinite fluid. A number of workers have been extending Einstein's analysis [3, 5]. Three approaches have been presented: the theoretical basis of viscosity computation, the effect of particle texture and shape, and the effect of concentration. Several relations have been developed for suspensions in with nearest neighbor interactions cannot be neglected. Guth and Simha [6] considered the first order effect of spheres interacting with one another. They found that:

$$\frac{\mu}{\mu_{\mathrm{o}}} = 1+2.5\phi+14.1\phi^2 \tag{9}$$

where μ is the viscosity of the suspension, μ_{o} is the viscosity of the pure solvent and ϕ is the volume fraction of spheres in the suspension. A later correction gave a value of 12.6 for the last constant [7].

Several authors have made experimental studies of the effects of concentration on the viscosity of suspension of spheres. The data they have proposed are considerably scattered. Thomas [8] has tried to find the sources of scatter in the data and found that scattering is caused in large part by variations in particle size. For small particle sizes (diameters $<$ 1–10 µm) colloidal forces become important and the viscosity begins to increase as particle size decreases. The viscosity is also shear rate-dependent in this case. For the particles larger than 1 to 10 µm, the particle Reynolds number becomes significant. The inertial effects results in an increase in relative viscosity with increasing particle size. Thomas has developed a unique curve, by eliminating diameter and shear rate effects. For low concentration data, such a graph can be represented by:

$$\frac{\mu}{\mu_{\mathrm{o}}} = 1+2.5\phi+11.4\phi^2 \tag{10}$$

where all the components are already defined.

The behavior of some specific systems has also been reported in the literature. Lin and Brodkey [9] studied rheological properties of

slurry fuel, concluding that they are shear-thinning under most conditions, but turn shear-thickening at extreme conditions. GRISKEY et al. [10] investigated the rheological behavior of cornstarch dispersions and found that they go from dilatant (shear-thickening) behavior at low shear rates to Newtonian behaviors at higher shear rates. The effect of particle aggregation on suspension has also been studied. DEVRIES [11] presented a number of experimental results concerning the particle aggregation in polymer lattices induced or accelerated by simple shear flow. No stable flow is possible under these conditions, and the apparent viscosity is an increasing function of the time of shearing.

3.1.3. Flow of Suspensions

Some flow patterns of relative interest will be reviewed. One of the most studied cases is that of transport of suspensions such as slurries through pipelines, due mainly to its occurrence in a wide number of industrial processes. Most of the theory developed for flow through tubes applies to laminar flow in smooth tubes. There are some relationships available for pressure-loss flow rate in purely viscous and viscoelastics flows. Relations for thixotropic and rheopectic systems appear not to be available.

Under the assumptions that purely viscous behavior prevails and that no slip occurs at the tube wall, the power-law equation for laminar flow is in the form [12]:

$$\tau_{\mathrm{w}} = \frac{D\Delta P}{4L} = K\prime\left[\frac{8v}{D}\right]^{n\prime} \tag{11}$$

where τ_w is the shearing stress at the wall of the tube, D is the tube diameter, ΔP is the pressure drop, L is the length of the tube, v the mean velocity, n' is the slope of the line when the data are plotted on logarithmic coordinates. For n' = 1, the fluid is Newtonian; for n' <1, pseudoplastic, or Bingham plastic if the curve does not go through the origin; and for n' >1, dilatant. The term K' is the consistency index; as the name suggest, the larger its value the thicker or more viscous the fluid.

The constant K' may be related to the analogous power-law constant K (see → Fluid Mechanics, Section 4.1.2) as follows [13]:

$$K' = K\left[\frac{3n'+1}{4n'}\right]^{n}\left[\frac{8v}{D}\right]^{n-n'} \tag{12}$$

if the fluid obeys the power-law, $n = n$' and:

$$K' = K\left[\frac{3n+1}{4n}\right]^{n} \tag{13}$$

Since Equation (11) rigorously portrays the laminar flow behavior of the fluid (provided n' and K' are evaluated at the correct shear stress), one may use it to define a Reynolds number applicable to all purely viscous fluids under laminar flow conditions. This dimensionless group can be derived simply by the substitution of $(D\Delta P/4L)$ from Equation (11) into the usual definition of the fanning friction factor, i.e.:

$$f = \frac{D\Delta P/4L}{\rho v^2/2} \tag{14}$$

such substitution leads to:

$$f = \frac{16\gamma}{D^{n\prime}v^{2-n\prime}\rho} \tag{15}$$

where $\gamma = K'8^{n'-1}$ and all the remaining component as already defined.

By letting $f = 16/Re$ as for Newtonian fluids in laminar flow, the above mentioned generalized Reynolds number can be obtained as:

$$Re* = \frac{D^{n'}v^{2-n'}\rho}{\gamma} \tag{16}$$

If the equation is desired in terms of K instead of K', Equation (12b) may be substituted into Equation (15) and:

$$Re* = \frac{D^{n}v^{2-n}\rho}{K8^{n-1}\left[\frac{3n+1}{4n}\right]^{n}} \tag{17}$$

For Newtonian fluids $n' = 1$ and $K' = \mu$, so γ reduces to μ and Re^* in Equation (16) transforms to the familiar $Dv/\rho/\mu$ showing that this traditional dimensionless group is merely a special restricted form of the more general described here.

Non-Newtonian fluids in turbulent flow generally show lower friction factors and, consequently, lower pressure drops than Newtonian fluids at corresponding Reynolds number. A detailed analysis of non-Newtonian flow at turbulent regime began with two papers published in 1959 by DODGE and METZNER [14] and SHAVER and MERRIL [15]. DODGE and METZNER used solutions of carboxymethyl cellulose and carbopal (a B. F. Goodrich soluble thickener), as well as clay

suspensions. They presented a viscous correlation in terms of parameters from shear-stress–shear-rate data and concluded that except for the carboxymethyl cellulose, the behavior of these materials could be correlated with the following generalization of the Newtonian friction factor:

$$\sqrt{\frac{1}{f}} = A_{1n}\log\left[\mathrm{Re}*(f)^{1-0.5n\prime}\right] + C_n^* \tag{18}$$

where A_{1n} and C_n' are parameters dependent on the flow-behavior index *n*. While the choice of power-law equation in the derivation requires that the Reynolds number used in Equation (17) be the power-law special case of Equation (16), it has been shown [14] that any errors due to this approximation are less important under turbulent flow conditions than in the laminar region. The utility of Equation (17) and of Reynolds number outside the laminar region has been shown diagrammatically in [14]. The authors found excellent agreement between experimental and extrapolated data. Furthermore, deviations from smooth curves were no greater for those fluids, which did not obey the power law, than for those which did. The parameters A_{1n} and C_n' in Equation (17) must be evaluated empirically, just as in the simpler case of Newtonian behavior.

By far, most of the study of the flow behavior of non-Newtonian suspensions has been devoted to monosized and monoshaped systems, mainly of spherical particle geometry. In reality, however, solid–liquid mixtures usually consist of dissolved solids with a variety of particle sizes, shapes, and concentrations. The available theory for the behavior of non-Newtonian suspensions is, therefore, of a limited application, and when dealing with real systems, empirical corrections are necessary to fully explain the suspension properties.

Studies of some real applications such as slurry transport are also encountered in the literature. The slurry to be transported may have settling or nonsettling characteristics. Sand in water, salt in benzene, and clay in drilling mud are typical examples of settling slurries, while paper pulp is a good example of nonsettling slurry. The law governing the settling rate of particles at low Reynolds numbers is the well know Stokes law. Settling phenomena of slurries in pipelines, as well as modifications of original Stokes law for flocculated suspensions and particles of odd shapes, have been studied by Thomas [16]. The turbulent regime is sometimes preferred to transport slurries within pipe in order to prevent settling, and to provide high throughputs. In this case, the viscosity of the suspension has been normally used to correlate the turbulence friction factors.

The problem of distribution and mixing of solids in turbulent slurry flow has been studied. The magnitude of flow velocity or Reynolds number required for maintaining turbulent mixing of solid–liquid slurries, may be computed from the following equation:

$$\frac{\rho v^2}{(\rho_\mathrm{s}-\rho)\,gx} = K\prime\left[\frac{\rho_\mathrm{m} v D}{\mu}\right]0.775 \tag{19}$$

where ρ is the liquid density, ρ_s the solid density, ρ_m the slurry density, v the minimum standard velocity, g the acceleration due to the gravity, D the mean particle diameter, μ the viscosity and K' a constant. When densities of solids and liquids are known, along with the volume fraction of solids in the slurry, the density of the mixture may be calculated by:

$$\rho_\mathrm{m} = C\rho_\mathrm{s} + (1-C)\,\rho \tag{20}$$

where C is the volume fraction of solids in the slurry. Equation (18) is recommended for mean diameters between 50 and 500 µm.

3.2. Flow Patterns in Hydrocyclones

The flow pattern in a hydrocyclone is complex. However, it is normally accepted that the hydrocyclone fluid flow consists of the three velocity components: tangential, vertical, and radial. Figure 4 shows a diagrammatically representation of these three velocity distributions within a hydrocyclone. With respect to the tangential component v_t, the linear velocity of the feed stream at the inlet point is given by:

$$v_\mathrm{t} = \frac{Q}{A_\mathrm{i}} \tag{21}$$

where Q is the volumetric flow rate and A_i is the area of the inlet nozzle.

Figure 4. Velocity distribution profiles within a hydrocyclone

As the flow develops in a spiral manner towards the air core, the circular speed increases as the diameter of rotation decreases. Under no friction loss conditions, the angular speed remains constant and is given by:

$$v_{\mathrm{t}} R = \text{constant} \tag{22}$$

where R is any radius of rotation.

In practical systems frictional losses result in a progressive decrease in tangential speed, thus Equation [21] needs to be modified, e.g.:

$$v_{\mathrm{t}} R^{n} = \text{constant} \tag{23}$$

where: $0<n<1$.

Experience has shown that the value of n decreases with increasing solids contents, with a maximum value of about 0.3 for solids contents of about 60 wt %. For normal operating conditions of 15 to 25 % of solids approximately, Trawinski[17] has suggested an average value of 0.5.

The maximum tangential velocity will occur in the secondary vortex immediately adjacent to the air core. Taking the proposed average value of 0.5, this maximum velocity will be theoretically described by:

$$v_{\mathrm{o}} = v_{\mathrm{t}} \left[\frac{D_{\mathrm{i}}}{D_{\mathrm{o}}} \right]^{1/2} \tag{24}$$

Practically, the limit on the maximum tangential velocity is given by pressure drop across the hydrocyclone. Under ideal conditions of no friction loss, the following relationship describes this maximum velocity:

$$v_{\mathrm{o}} = \left[\frac{2\Delta P}{\rho_{\mathrm{m}}} \right]^{1/2} \tag{25}$$

where ΔP is the pressure drop and ρ_{m} is the density of the slurry. As can be seen from Figure 4b, the profile of the vertical velocity component shows a well-defined position of zero velocity outside of which there is a low speed downwards, and inside of which the flow is much higher and upwards. This locus of zero vertical velocity (LZVV) follows the profile of the cyclone.

The radial component of velocity is inward, and accurate measurement of it is difficult because its magnitude is small. Apparently, such speed decreases proportionally to radius decreasing, from a value that can be expressed by:

$$v_{\mathrm{r}} = w \tan \left[\frac{\theta}{2} \right] \tag{26}$$

where w is the vertical velocity at the wall and θ is the angle of the cone.

The radial position at which this velocity falls to zero is not known precisely. Figure 4c shows the radial component of velocity.

3.3. Mechanisms of Particle Separation

According to the flow patterns just described, several models to explain the actual mechanism of particle separation have been developed. Each model works well for particular hydrocyclones only, the models are not of general application, because every one relies on a single dominant feature of the flow inside the hydrocyclone. There have been at least four approaches to describe the behavior of particles in a hydrocyclone: the equilibrium-orbit theory, the residence-time theory, the crowding theory and the turbulent two-phase theory.

3.3.1. Equilibrium-Orbit Theory

An equilibrium orbit is proposed at a radius position, at which the inward drag on the particle due to the inward radial velocity of the fluid counterbalances the outward force to the liquid rotation, i.e.:

$$\frac{\pi x^3}{6}\left(\rho_s - \rho\right)\frac{v_t^2}{R} = 3\pi\mu v_r x \tag{27}$$

or:

$$\frac{x^2}{18}\frac{\left(\rho_s - \rho\right)}{\mu} = \frac{R v_r}{v_t^2} \tag{28}$$

where x is the particle diameter or size, and the densities and velocities are as previously defined. If $v_t \sim (v/R^n)$ and $v_r \sim (v/R^m)$, where v is the inlet velocity, then:

$$\frac{x^2}{18}\left[\frac{\rho_s - \rho}{\mu}\right] = \left[\frac{K}{v}\right] R^{1+2n-m} \tag{29}$$

For given inlet velocity and liquid, the radius of the orbit is proportional to the particle size. If R is greater than the radial position for zero vertical velocity, it is assumed that all particles will be collected. If R is less than the radial position, all particles will be carried away in the underflow. Thus, a particle will have a 50 % chance of removal if the radius of its equilibrium orbit is equal to that of the zero vertical velocity. Using this approach, Bradley [7] derived a relation making assumptions to the position of the locus of zero vertical velocity profile.

3.3.2. Residence-Time Theory

This theory advocates the importance of the time spent in the hydrocyclone. Assuming the spiral has a constant velocity equal to the average inlet velocity, and supposing the liquid follows N complete spirals at an average radius R_{av}, the residence time will be:

$$t = \left[\frac{2\pi R_{av}}{v}\right] N \tag{30}$$

a particle of size x will travel a distance L in this time t where:

$$\frac{L}{t} = v = \frac{x^2\left(\rho_s - \rho\right)}{18\mu}\left[\frac{v^2}{R}\right] \tag{31}$$

Combining Equations 30 and 31 the following relationship is obtained:

$$x^2 = \frac{9\mu L}{N\pi v\left(\rho_s - \rho\right)} \tag{32}$$

This is a form similar to Equation 29 without the dependence on radial positions.

Using direct analogy with gravity settling, Trawinski [22] proposed another simple approach, which may be considered as a variation of the residence-time theory. He reported the following equation:

$$x_c = \left[\frac{18\mu q}{g\left(\rho_s - \rho\right) Z}\right]^{1/2} \tag{33}$$

where x_c is known as the cut point, q equals (Q/A) and Z is the acceleration factor. Including further considerations, e.g., for capacity and the separating area (surface of the cylinder formed by the air core), Trawinski [17] also proposed:

$$x_c = k_1\left[\frac{18\mu}{\left(\rho_s - \rho\right) g}\right]^{1/2}\left[\frac{D_c D_i}{l}\right]^{1/2}(H)^{-0.25} \tag{34}$$

where k_1 is a constant, H is the liquid head, and all the geometric characteristics are as defined in Figure 2.

3.3.3. Crowding Theory

Due originally to Fahlstrom [18], this theory proposes that the cut size is a function of the capacity of the underflow orifice and the particle size distribution. The crowding effect can swamp the primary interaction to the extent that the cut size can be estimated from the mass recovery to the underflow. The support to this theory has been given mainly by Bloor And Ingham [19], by means of the mathematical models developed to describe the fluid mechanics of hydrocyclones.

3.3.4. Turbulent Two-phase Flow Theory

This theory states the importance of the effect caused by turbulent flow in hydrocyclones. According to this, it is proposed that separation takes place under the influence of the centrifugal field and the turbulent transport in the two-phase flow. The influence of turbulence can be described by an eddy diffusion coefficient equal to, or smaller than the diffusion of the fluid particles. The assessment of the influence of such diffusion on separation is very difficult in practice.

Bloor and Ingham [19] have also contributed to the theoretical background of this theory. They derived an analytical form of the radial velocity and found an analytical solution to the equation of motion for the tangential speed. They also developed a more elaborated and physically realistic model, for the eddy viscosity based on the Prandtl mixing theory, which greatly simplified the equation of motion.

Schubert and Neesse [20] proposed a set of equations and derived two models for turbulent cross-flow wet classification: the suspension-partition model and the suspension-tapping model. In the former the flow is divided into overflow and underflow without changes in the total cross-section, whereas in the latter overflow and underflow are tapped from the main flow through small outlet openings. According to them, the suspension-tapping model is analogously applicable to the separation in hydrocyclones.

3.4. Characteristics of Performance of Hydrocyclones

The most important features of performance of hydrocyclones are the particle cut size, the pressure drop and the volume throughput. Previous work has established the cut size as the best way to predict efficiency in hydrocyclones. In order to understand and utilize the cut size concept, it is necessary to deal with at least two topics, i.e., particle size analysis and efficiency of solid–liquid separation (see → Particle Size Analysis and Characterization of a Classification Process; → Solid–Liquid Separation, Introduction).

3.4.1. Separation Efficiency, Cut Size

The solid phase of suspensions to be treated in solid–liquid separation equipment generally consists of an immense number of particles of diverse sizes and shapes. All this population of particles needs to be identified or characterized. The frequency of occurrence of particles of every size present, arranged and presented in a statistical manner, is known as the particle size distribution. The most common way of presenting such distributions as well as the types of distributions important to particles technology, can be found in the specialized literature [21, 22] (see → Particle Size Analysis and Characterization of a Classification Process).

In solid–liquid separation it is important to know the particle size distribution in order to identify which part of it will be separated, and transform this quantity in a measure of efficiency (→ Particle Size Analysis and Characterization of a Classification Process, Section 2.1). The common way of presenting particle size data for solid–liquid separation purposes is in form of a plot. The most common ones are equivalent sphere diameters, equivalent circle diameter, and statistical diameters. The equivalent sphere diameter is the diameter of a sphere which has the same property as the particle itself. Such a property could be the settling velocity. A diameter derived from the settling velocity is known as Stokes diameter and is a very useful quantity for solid–liquid separation, especially to those techniques in which the particle motion relative to the fluid is the governing mechanism.

The amount of particle matter which belongs to specified size classes on the particle axis may be also represented in several ways. Number of particles and mass of particles are the most commons ones, but surface area and volume are used as well. For solid–liquid separation techniques, the most convenient form of expressing amount of particle matter is by mass, because the balances necessary to define performance are normally mass balances.

In general, particle size distributions can be presented as frequencies, *f(x)*, or cumulative frequencies, *F(x)*, which are related to each other by following equation:

$$f(x) = \frac{dF(x)}{dx} \tag{35}$$

the graphical representation of a particle size distribution is usually plotted in a cumulative form. In a typical cumulative plot, points are entered showing the amount of particulate material contributed by particles below or above a specified size. Hence, the curve presents a continuously rising or deceasing character. These oversize and undersize distributions, as illustrated in Figure 5, are simply related by:

$$F(x)_{\text{oversize}} = 1 - F(x) \tag{36}$$

where *F(x)* is the cumulative fraction undersize.

Figure 5. Relationship between frequency and cumulative distributions

A cumulative plot will, therefore, include a broad range of particle sizes. It is often convenient, however, to refer to a single characteristic size for system. Many characteristic sizes have been proposed, most of them involving a mathematical formula. An important one, which can be read off any cumulative plot of the particle size data, is the median particle size. It is defined as that particle size for which the particle amount equals 50 % of the total. If the particle size is represented by number, such point is called the number median size. If mass is used as the measure of particle amount, this parameter is known as the mass median size. The distribution between number and mass median is very important, since they differ generally by a considerable amount. Such difference means that number and mass cumulative plots do not agree for the same system of particles. The weight of a particle, which varies as the cube of its diameter, accounts for this mentioned disagreement.

For practical purposes, it is reasonable to fit an analytical function to experimental particle size distribution data, and then handle this function mathematically in further treatment. It is, for example, very much easier to evaluate mean sizes from analytical functions from experimental data. Several different distribution functions can be found in the literature (→ Particle Size Analysis and Characterization of a Classification Process, Section 2.3). An exhaustive review of some of them has been presented [23].

The *normal distribution* is widely used in most fields of science for the representation of populations. The normal distribution function is given by:

$$y = \frac{1}{\sigma\sqrt{2\pi}} \exp\left[-\frac{(x-a)^2}{2\sigma^2}\right] \tag{37}$$

where y is the probability density, x the diameter of the particle, a the arithmetic mean, and σ the standard deviation. From the normal function, if the arithmetic mean a is zero, the probability of occurrence within the interval form the mean (zero) to the value x, i.e., $F(x)$ is given by the *error function*:

$$F(x) = \frac{1}{\sigma\sqrt{2\pi}} \int_0^x \exp\left[-\frac{x^2}{2\sigma^2}\right] dx \tag{38}$$

where σ and x have the same meaning as described in the normal function.

Materials with a normal distribution of particle size are relatively rare and are found chiefly among the particulates produced by chemical processes like condensation or precipitation. The importance of this function, however, is that it provides an idealized error distribution built upon the assumption that elementary errors or small causes combine at random to produce the observed effect.

The *log-normal distribution* is probably the most widely used type of function; it is again a two-parameter function, it is skewed to the right and it gives equal probability to ratios of sizes rather than to size differences, as in the normal distribution. Furthermore, the log-normal function is the most useful one among the different types of functions. It can be expressed in the following form:

$$f(x) = \frac{1}{x \ln\sigma_g \sqrt{2\pi}} \exp\left[-\frac{(\ln x - \ln x_g)^2}{2\ln^2\sigma_g}\right] \tag{39}$$

where $f(x)$ is the size distribution function for particle size x, x_g is the geometric mean of the distribution, and σ_g the geometric standard deviation of $\ln x$.

The log-normal distribution has the important advantage of ease of conversion from one type of size distribution to another. It can be shown mathematically that all four particle size distributions, by number, length, surface, and volume (mass), when plotted on log-probability paper are parallel lines with equal linear spacing.

The *Rosin–Rammler distribution* function is another equation widely used in particle size measurement. It is a two-parameter function, usually given as cumulative percentage oversize:

$$F(x) = \exp\left[-\left(\frac{x}{x_r}\right)^n\right] \tag{40}$$

where x_r is a constant giving a measure of the particle size range present and n is another constant characteristic of the material under analysis and gives a measure of the steepness of the cumulative curve. The frequency distribution is obtained by differentiation of Equation 40, which can be reduced to:

$$\log\left[\ln\frac{1}{F(x)}\right] = n\log x - n\log x_r \tag{41}$$

which gives a straight line if $\log(\ln 1/F/(x))$ is plotted against $\ln x$. This is the basis for the Rosin–Rammler graph paper because it is the size corresponding to $100/e = 36.8\%$ and n is the slope of the line. Rosin–Rammler charts from German sources contain edge scales, which with the aid of a parallel rule allow direct estimation of n. For accurate work, the use of large sizes (32.4×25.4 cm) charts designed by Harris [24] is recommended. The various mean sizes available may be easily calculated from the Rosin–Rammler equation; they all involve mathematical tables.

The *Harris model* is a three-parameter equation, which is very versatile and fits many empirical size distributions. Harris [24] showed that most of the widely used two-parameter equations are in fact special cases of the equation:

$$F(x) = \left[1 - \left(\frac{x}{x_o}\right)^s\right]^r \tag{42}$$

where *F(x)* is cumulative percentage oversize, x_o is the maximum size in the sample, s is a parameter concerned with the slope of the log–ln plot in the fine region and r is a parameter concerned with the shape of the log–ln plot in the coarse region.

The ways for measuring particle size are diverse and have been largely improved in recent years. Sieving and sedimentation are the traditional ones, but microscopy, laser diffraction, and stream scanning techniques are currently spreading and finding applications. Several methods for analytical determination of particle size analysis have been reviewed [23]. Although the most novel techniques have the advantage of quick response, they have proved to be very selective. Therefore, most of them are of quite limited application. A rule of thumb should be to use the analytical technique whose indirect measurement agrees, as much as possible, with the specific application. For example, in solid–liquid separations one is concerned with particles settling by gravitational forces, so techniques using this sort of forces to evaluate particle size distribution would be most appropriate.

To evaluate the efficiency of separation it is necessary to take into account that solid–liquid separation is basically an imperfect process. Whereas the underflow is always wet slurry, the overflow can be considered as a turbid liquid. This general behavior is critic in hydrocyclones, as they always, despite the presence of solids in the liquid, will split the flow into two streams. Therefore, the aim of operation of a hydrocyclone will be not only to obtain the above-mentioned slurry, but also to deliver is as free from liquid as possible. Equally, for clarification purposes, the overflow should be drawn from the hydrocyclone with the least possible concentration of solids. As Tenberger and Rietema [25] have stated, a single efficiency number can never be capable of fully describe the result of separation, except when it is ideal.

The imperfection of solid–liquid separation has caused the need to express efficiency by different means. A good review of these mentioned efficiencies is presented in [26].

The first and most obvious definition of separation efficiency is simply the overall mass recovery as a fraction of the feed flow rate. According to Figure 6:

$$E_t = \frac{M_c}{M} \tag{43}$$

where all the components are as defined in Figure 6.

If there is no accumulation of solids in the separator then:

$$M = M_c + M_f \tag{44}$$

and there is a choice of three possible combinations of the material streams for the total efficiency testing. It can be shown [3] that if all the operating conditions are equal, the most accurate estimation of the local efficiency comes from the two leaving streams.

As has been already mentioned, hydrocyclones act as flow dividers. Thus, they also split the solids in at least the same ratio, as is the ratio of underflow to throughput, R_f:

$$R_f = \frac{U}{Q} \tag{45}$$

Figure 6. Schematic diagram of a separator. M: mass flow rate of solids in the feed, M_c: mass flow rate of separated solids, M_f: mass flow rate of nonseparated solids, $F(x)$: cumulative percentage oversize of feed solids, $F_c(x)$: cumulative percentage oversize of separated solids, $F_f(x)$: cumulative percentage oversize of nonseparated solids, Q: volumetric flow rate of feed suspension, U: volumetric flow rate of underflow suspension, O: volumetric flow rate of overflow suspension

The total efficiency defined in Equation 43 will thus include the effect of this flow splitting known as dead flux. For this reason, a better way of expressing efficiency of separators such as hydrocyclones, is by means of a reduced efficiency which has been defined as:

$$E\prime_t = \frac{E_t - R_f}{1 - R_f} \tag{46}$$

If complete separation is achieved, providing that there is no accumulation of solids, the value of the total efficiency from Equation 43 will be the unit, and so will be the value of the reduced total efficiency. If, on the other hand, there is no separation at all, E_t will equal R_f in order to satisfy the requirements of an efficiency definition, leading to a value of zero in Equation 46.

The total efficiency defined by Equation 43 includes all particle sizes present in the feed solids. If only a narrow range of particle sizes is of interest, another efficiency of separation particular to that range can be defined. A mathematical expression of such partial efficiency is:

$$E_p = \left[\frac{M_c}{M}\right]_{x_1/x_2} \tag{47}$$

where x_1 and x_2 represent the particle size limits of a definite range.

If the particle size range in Equation 47 becomes infinitesimal, the obtained efficiency corresponds to a single particle size x and it is known as the grade efficiency, defined by:

$$G(x) = \left[\frac{M_c}{M}\right]_x \tag{48}$$

The grade efficiency has become a very useful definition, because most industrial powders consist of an infinite number of differently sized particles. Thus, a single particle size really corresponds to a range of particles having almost similar sizes. Therefore, the grade efficiency of most separation equipments is a continuous function of x. This function is seldom expressed analytically but graphically. An S-shaped curve is usually obtained for separators like hydrocyclones, in which inertial or gravity body forces perform the separation.

As the value of the grade efficiency has the character of probability, plotting the probability for any given size fraction against particle size would give a curve as known in Figure 7. This sort of curve is normally called a grade efficiency curve.

Figure 7. Grade efficiency and reduced grade efficiency curve for hydrocyclones

A grade efficiency curve for hydrocyclone is derived from screen analysis data on the feed, overflow and underflow streams. As mentioned before, it is practically impossible to fraction common systems of particles in a finite number of sizes. It can be shown [27] that a practical grade efficiency curve is really derived from a stepwise calculation, drawing a line through the midpoints of size intervals. A curve thus derived does not pass through the origin. This can be explained bearing in mind that, as has been previously emphasized, a hydrocyclone is a flow divider, so the underflow always contains a certain quantity of very fine particles which simply follow the flow, and are split in the same ratio as the liquid. The apparently finite efficiency for

fine particles is, therefore, equal to the underflow to throughput ratio R_f as shown in Figure 7. A reduced grade efficiency, similar to the reduced efficiency represented by Equation 46 can then be obtained as:

$$G'(x) = \frac{G(x) - R_f}{1 - R_f} \tag{49}$$

As can be seen in Figure 7, the correspondent curve to this definition does cross the origin.

Hydrocyclones are among those equipments whose separation performance is highly dependent on particle size. Thus, according to this, an overall efficiency of separation is not the best way to evaluate their performance. For this reason, it is advisable to express their efficiency for each size of particle in the range measured. As experience has shown, the only single number, which in some way gives the separation power of a hydrocyclone, is the *cut size* x_{50} (for a definition of cut size see → Particle Size Analysis and Characterization of a Classification Process, Section 3.1.4). All particles above the cut size will be generally going to the underflow, whereas those below the cut size will be normally reported to the overflow.

As can be concluded, the cut size is derived from a grade efficiency curve. As the calculation and plotting of a full grade efficiency curve is a time-consuming task, alternative ways of determining the cut size have been proposed [28, 29].

The *sharpness of separation* can be related to the shape of the curve in a number of manners. Knowing the grade efficiency curve, comparisons of classification sharpness of different equipments can be made by plotting *G(x)* against the dimensionless size x/x_{50}, and comparing the resultant normalized curves. To define the curve steepness, a ratio of two sizes corresponding to two different percentages on the grade efficiency curve on either side, and 50 % equidistant, can be used. This parameter is called the *sharpness index* and is represented by:

$$H_{25/75} = \left[\frac{x_{25}}{x_{75}}\right] \tag{50}$$

It was previously stated that the grade efficiency curve does not go through the origin. The cut size as has been defined is derived from this curve. If, in order to practically assess the performance of hydrocyclones, a reduced grade efficiency curve is used, the particle size which gives a 50 % efficiency in such a curve is called the reduced cut size and is represented by x'_{50}.

The maximum obtainable efficiency related to particle size would be that minimum particle size with 100 % probability of being reported to the underflow. Graphically, by extrapolating the end part of the curve to the horizontal axis, such size will be obtained. It has been proved that in practice, the maximum of the efficiency is around 98 %, and the minimum size correspondent to this efficiency is represented by x_{98} and known as the approximate limit of separation.

Several correlations have been proposed in literature to evaluate the cut size. They are either empirical or theoretical, and are expressed in the traditional British System of units, as well as in SI units, even in both. Perhaps the most important criterion for classifying the proposed correlation for cut size, is by dividing them into two groups considering whether the feed concentration has been taken into account. The main correlations, which do not consider the feed concentration as a variable, will be reviewed as follows.

Bradley [2] proposed:

$$x_{50} = \left[\frac{18\pi\mu(1-R_f)}{16LQ(\rho_s-\rho)}\right]^{1/2} \left[\frac{2.3D_o}{D_c}\right]^n \left[\frac{D_i^2}{\alpha}\right] \tag{51}$$

where Q is the flow rate, D_o, D_c and D_i are the dimensions defined in Figure 2, and (and n are empirical constants depending on the cyclone design and the fluid properties.

Rietema [30] derived a dimensionless, characteristic cyclone number C_{y50} represented by:

$$C_{y50} = x_{50}^2\,(\rho_s - \rho)\,\frac{L\Delta P}{\mu\rho Q} \tag{52}$$

where ΔP is the pressure drop. C_{y50} is determined experimentally and is not directly related to the more important hydrocyclone variables. However, Rietema has demonstrated the usefulness of the parameter and quotes a value of 3.50 for optimal separation, corresponding to the conditions: $L/D_c = 5$, $D_i/D_c = 0.28$, $D_o/D_c = 0.34$ and $l/D_c = 0.4$, where all the dimensions are as defined in Figure 2.

Dahlstrom [31] proposed:

$$x_{50} = \frac{C(D_o D_i)^{0.68}}{Q^{0.53}} \left[\frac{1.73}{\rho_s - \rho}\right]^{1/2} \tag{53}$$

where C is a constant sensitive only to major changes in the cyclone dimensions. This equation holds well for cyclones in which the length

of the cylindrical section equals that of the cone, and has been shown to hold for diameters of 3 to 14 inches (7.5 to 35 cm), for flows containing up to 20 % solids by weight.

Yoshioka and Hotta [32] developed an equation based on the orbital concept and equilibrium cone surface defined by the end of the vortex finder and the cone apex. The equation is:

$$x_{50} = 0.2 D_c^{0.1} D_i^{0.6} D_o^{0.8} \left[\frac{\mu}{Q(\rho_s - \rho)} \right]^{1/2} \tag{54}$$

which is expressed in SI units; the constant 0.2 was experimentally evaluated.

De Gelder [33] has derived an equation, which does not include experimental values:

$$x_0 = D_o \left[\frac{0.349 Re(D_c - kD_o)}{D_i} \right] \left[\frac{\rho_s}{\rho} - 1 \right]^{1/2} \tag{55}$$

where *Re* is the Reynolds number, x_0 is the diameter of particle which is just not collected, i.e., with centrifugal efficiency of 0 % and *k* is a constant, function of $D_i^2/D_o D_c$. Although Equation 55 was first developed for gas cyclones, it is said to hold well for hydrocyclones.

Lynch and Rao [34] presented the following empirical correlation:

$$\log x\prime_{50} = \frac{D_o}{2.6} - \frac{D_u}{3.5} + \frac{\Delta P}{10.7} - \frac{Ql_o}{52} + K \tag{56}$$

where x_{50}^* is in micrometers, D_o and D_u are in inches, ΔP is in pounds per square inch (psi), Ql_o (mass flow rate of the liquid in the overflow) is in ton/h, and *K* is a function of the material and the hydrocyclone (2.0 for silica and 2.5 for copper ore).

3.4.2. Capacity, Pressure Drop

The capacity of a hydrocyclone can be evaluated in terms of the volume flow rate delivered, also known as throughput, which depends on the available pressure drop. Thus, there is a loss of pressure across the unit. The pressure drop is an important variable and is more easily defined than efficiency. Relationships between Q and ΔP can be developed by means of established theory for the flow of liquids in pipes. There are a number of pressure drop correlations reported in the literature, some of which will be described.

Trawinski [35] proposed the correlation:

$$Q = K D_i D_o \left[\frac{\Delta P_g}{\rho} \right]^{1/2} \tag{57}$$

where *K* is a factor, which contains diameter ratios, fraction loss, and cone angle variables. For $\theta = 15° - 30°$, *K* equals 0.5.

Bradley's approach [2] leads to the following expression:

$$\frac{(\Delta P/\rho)}{(v_i^2/2g)} = \frac{\alpha^2}{n} \left[(D_c/D_o)^{2n} - 1 \right] \tag{58}$$

where the left-hand side group is the pressure difference in terms of inlet velocity heads and α is the inlet velocity loss coefficient v_c/v_i whereas *n* is the power from Equation 23.

4. Effect of Variables on Hydrocyclone Performance

A single conclusion can be made from the previously survey: the operation of hydrocyclones is quite complex. There is not a unified theory to fully explain the mechanisms of flow and particle separation inside a hydrocyclone. It is normally accepted that the overall behavior of the particles of solids inside a unit will depend on factors contributed by the liquid, by the solid, and by the apparatus design. These factors may be interrelated or independent of each other. In order to study the effect of such factors upon the performance of hydrocyclone units, they have been usually divided into operational variables and design variables.

4.1. Operation Variables

First of all, a pressure drop must exist in order to drive the feed suspension across the unit. An increment in this pressure drop will decrease the cut size as well as increase the sharpness of separation and flow rate. According to this, great mass recoveries could be obtained raising the pressure drop. Although such fact is literally true, it is normally an uneconomical measure because large pressure loss increases are necessary. As has been mentioned earlier, practical values of pressure drop range between 0.34 and 6 bar. However, for small cyclones, Trawinski [27] has suggested an upper limit of 4 bar. As in other separation techniques, a finite density

difference between the phases involved is essentially necessary. Without it, no separation can be achieved. As expected, experience has shown an increase in separation efficiency as the density difference increases.

The effect of feed solids concentration on separation performance is well recognized in practice. Generally, increasing input concentrations reduces the total efficiency. Svarovsky and Marasinghe [36] have proposed a semiempirical correlation, which allows scale-up prediction of performance with feed concentrations higher than 8 vol %. Neesse et al. [37] compared dilute flow (low solids concentration of the feed) and dense flow (high solids concentration of the feed) separations, focusing their study on the effect of turbulence.

Perhaps the least understood effect on performance of a hydrocyclone is that of the viscosity. Very little quantitative information exists on the literature about it. It is normally accepted that viscosity has little effect on separation efficiency. From simple theory it can be proved that medium viscosity will only have an effect at low Reynolds numbers (i.e., laminar flow), but because turbulence is promoted by pumping, the effect of viscosity will only be appreciable when the flow is forced by static head or in very large units. Nappier-Munn [38] found concordance with theory about viscosity effects, while Williamson et al. [39] studied the effect of viscosity, along with pressure drop, in reducing the minimum cut size of particles that can be separated effectively. They found that cut size falls as the pressure drop rises and as viscosity is reduced.

The effect of less common variables has also been studied. Fontein et al. [40] examined the influence of some uncommon parameters such as the roughness of the cyclone wall, as well as the shape of the solid particles on suspension. They found that rough-walled cyclones show lower efficiencies than smooth-walled ones. According to them, this is mainly due to the fact the rotation flow is greatly retarded by the rough wall, thus decreasing the centrifugal force, which affects separation.

4.2. Design Variables

Some modifications and recommendations about the geometry of hydrocyclones have appeared in the literature, mainly from manufactures. Despite many variations in design and suggestions for varied configurations, the so-called standard cyclones, such as the Rietema cyclone, have proved the most efficient in separation and capacity.

The most common materials of construction are steel, aluminum oxide, ceramics, polyurethane, and other plastics. Sometimes the inner body is lined with hard materials in order to minimize wear caused by operation. Soft rubber is popular and suitable where temperatures do not exceed 60°C and where hydrocarbon oils or solvents are absent. Ceramic liners can also be used. Wear-resistant metals are useful when particle sizes are above 100 μm or where tramp material is suspected, which could damage rubber linings. With temperatures above 60 °C or in presence of hydrocarbons, neoprene or nitrile, as well as polyurethane rubbers have been successfully employed.

The effects of some geometry variables on hydrocyclone performance are shown in Table 1.

Table 1. Effects of some design variables on hydrocyclone performance

Variable	Effect
Cyclone diameter increases	cut size increases, pressure drop usually decreases
Cyclone inlet diameter increases	gravity force in cyclone decreases, cut size increases, capacity falls, pressure drop decreases
Overflow diameter increases	cut size increases, risk of coarse sizes evident
Underflow diameter increases	brings excess fines from liquid phase into underflow
Cyclone shape becomes longer	decreases cut size sharpness separation
Cyclone wall become rougher	capacity increases, efficiency decreases

5. Selection and Design of Hydrocyclone Systems

Hydrocyclones differ from other solid–liquid separation equipments as they have a broad number of variables involved in their operation. The influence of some variables is not completely understood, and their effect may be completely

different from one unit to another. Theses are some of the reasons why the task of selecting a hydrocyclone system is difficult to deal with. Generalizations of performance characteristics can seldom be made, and the choice necessarily relies upon semiempirical relationships or models, which are, inevitably, of limited application. In selecting or designing hydrocyclones for a specific duty, the recommended way is either using manufactures catalogues or to make calculations to obtain cut point and throughputs.

5.1. Analytical Solutions

The previously cited formulae for the computation of cut points and capacities can be employed as a first approximation. The actual choice can be mainly based on the function to be performed by the system. In classification applications, for instance, the cut size is usually fixed and the design is simply based upon achieving that cut size. On the other hand, in separation, a certain degree of efficiency is normally required, and the resulting design must be a compromise between technical and economical considerations. The adaptability to industrial scale can represent a real problem. Moir [41] pointed out that some of the correlations for calculating cut points and throughputs for cyclones might not be suitable for industrial problems, since they were developed using slurries with low solids contents and small units. An alternative to high capacities is use of multiple hydrocyclone systems for industrial production. Gerrard and Liddle [42] have described two methods for selection of units to be used in parallel for a given duty. Many other authors have mentioned the advantage of using multicyclone systems.

5.2. Graphical Solutions

A series of charts or nomographs have been also developed for the estimation of effects of changes in operating variables on performance of hydrocyclones. Zanker [43] presented a series of equations incorporated into some nomographs in order to make trial-and-error calculations faster. Rao and Nageswararao [44] simplified the use of charts to just one nomograph. Again, combined with some calculations, they claimed such a graph to be a useful tool in selecting hydrocyclones for specific duties. Another proposed graphical method is given in [45]. The authors emphasized, however, that application of the technique should be for guidance purposes only.

5.3. Manufactures' Choice

Several equipment manufactures have published literature about selection of hydrocyclones in the form of brochures, technical reports, and so on. In many International Conferences held around the world some manufactures present papers about selection, innovations, etc., as well as table-top exhibitions of their available equipment.

Table 2. Summary of some known hydrocyclone designs

Cyclone type and size of hydrocyclone	D_i/D_c	D_o/D_c	l/D_c	L/D_c	θ	$Stk_{50}Eu^{**}$	$K_p{}^{**}$	$n_p{}^{**}$
Rietema's design* D_c = 0.075 m	0.280	0.340	0.40	5.00	20°	0.0611	24.38	0.3748
Bradley's designD_c = 0.038 m	0.133	0.200	0.33	6.85	9°	0.1111	446.5	0.3230
Mozley cyclone 1D_c = 0.022 m	0.154	0.214	0.57	7.43	6°	0.1203	6381	0
Mozley cyclone 2D_c = 0.044 m	0.160	0.250	0.57	7.71	6°	0.1508	4451	0

5.4. Dimensionless Scale-Up of Hydrocyclones

5.4.1. Introduction

Because of the hydrocyclones' inflexibility, the methods of selection just reviewed can be only used as an approximation. The correlations proposed are often derived from studies of effects of geometrical proportions on capacity and separation efficiency. In this sense, if literature on hydrocyclones is rigidly followed when designing a unit, it might lead to a unique hydrocyclone choice, whose geometry could has been never tested before, so reliable prediction of its performance may be misleading. Based on this and many other facts and factors, a scale-up procedure to select hydrocyclones, attributed mainly to SVAROVSKY [1] has been proposed. The method consists of selecting a known design of hydrocyclone and, by using a series of dimensionless relations, making the necessary predictions as changes on fixed variables are introduced. A summary of some known hydrocyclone designs is presented in Table 2.

As the performance characteristics of hydrocyclones involve a great number of variables, the use of dimensionless groups in this method is an obvious advantage. The basic concepts underlying dimensionless analysis and scale-up procedures have been used for long time in classical mechanics principally. Perhaps the most common method of dimensional analysis is that attributed to LORD RAYLEIGH known as the Pi theorem. The basic steps of dimensional analysis can be found in (→ Scale-Up in Chemical Engineering) [43].

5.4.2. Definition and Derivation of Dimensionless Groups for Hydrocyclones

In the case of hydrocyclones, selection and operation is based on the relationships between the pressure drop and flow rate and the relationship between separation efficiency and flow rate. The pressure drop versus volumetric flow rate relationship is usually expressed as $Eu = f\,(\mathrm{Re})$, where *Eu* is the Euler number. These dimensionless groups are graphically related as shown in Figure 8. The Euler number is in fact a pressure loss factor, easily defined as the limit on the maximum characteristic velocity v obtained by a certain pressure drop ΔP across the hydrocyclone. It can be expressed as:

$$Eu = \frac{2\Delta P}{\rho v^2} \tag{59}$$

where ρ is the density of the fluid.

Figure 8. A typical plot of *Eu* versus *Re* for hydrocyclones

The Reynolds number defines flow characteristic of the system and in the case of hydrocyclones, the characteristic dimension may be taken as the cyclone body diameter D_c, i.e.:

$$Re = \frac{D_c v \rho}{\mu} \tag{60}$$

where μ is the medium viscosity.

The relationship between separation efficiency and flow rate is not significantly influenced by operational variables, so it is commonly expressed in terms of cut size x_{50}. The use of the cut size to define efficiency of hydrocyclone is of the utmost importance since, as has been previously emphasized their performance is highly dependent on particle size. Since cut size implies size of particles likely to be separated, it follows that such particles must be influenced by forces exercised on the suspension. The forces developed in a hydrocyclone can be analyzed by sedimentation theory, and a dimensionless group thus derived, the Stokes number, will include cut size.

The Stokes number is a very useful theoretical tool and, for the case of hydrocyclones, its derivation may be carried out as follows. Considering a settling tank of length L and wide W, it would have a settling area of $A = LW$, and if the depth is H, then the retention volume is $V =$

AH. With a flow through the tank of Q (m^3/h), the detention time is given by:

$$t_{\mathrm{d}} = \frac{V}{Q} \tag{61}$$

Particles to be removed must settle, under gravity influence, through the depth H requiring t_{s}, where:

$$t_{\mathrm{s}} = \frac{H}{u_{\mathrm{t}}} \tag{62}$$

u_{t} being the settling rate defined by Equation 6.

Only particles for which t_{s} is equal or less than t_{d} will be removed. Hence, by equating t_{s} and t_{d} a cut point or separation mesh is defined as:

$$\frac{H}{u_{\mathrm{t}}} = \frac{V}{Q} \tag{63}$$

transposing for u_{t}:

$$u_{\mathrm{t}} = \frac{HQ}{V} = \frac{Q}{A} \tag{64}$$

If Equation 64 is then equated to Equation 6, the limiting size of particles to be settled can be derived giving:

$$x^2 = \frac{18\mu Q}{g\left(\rho_{\mathrm{s}} - \rho\right) A} \tag{65}$$

For centrifugal systems the same replacement done in Equation 6 leads to:

$$x^2 = \frac{18\mu Q}{R\omega^2\left(\rho_{\mathrm{s}} - \rho\right) A} \tag{66}$$

Since $\omega = v_t/R$, where v_{t} is the tangential velocity of the particle, Equation 66 can also be expressed as:

$$x^2 = \frac{18\mu QR}{v_t^2\left(\rho_{\mathrm{s}} - \rho\right) A} \tag{67}$$

The radial settling velocity in a hydrocyclone is due to the centrifugal acceleration, which is proportional to the square of the tangential velocity of the particle and indirectly proportional to the radius of the particle position. As the tangential motion of the particle is unopposed, the tangential particle velocity can be taken as equal to the tangential component of the fluid velocity at the same point. For the same flow regime, the velocities anywhere in the flow in a hydrocyclone are proportional to a characteristic velocity v while the position radii are proportional to the cyclone diameter D_{c}. Under such assumptions Equation 67 can be approximated to:

$$x^2 = \frac{18\mu Q D_{\mathrm{c}}}{v^2\left(\rho_{\mathrm{s}} - \rho\right) A} \tag{68}$$

Considering the superficial velocity in the hydrocyclone body as the characteristic velocity, the volumetric flow rate equals $\left(v\pi D_c^2\right)/4$, also $A = \pi D_c^2/4$ for the cyclone body. Thus, substituting Q and A into Equation 68:

$$x^2 = \frac{18\mu D_{\mathrm{c}}}{v\left(\rho_{\mathrm{s}} - \rho\right)} \tag{69}$$

Rearranging Equation 69 to express it in terms of inertial forces and hydrodynamic forces; the dimensionless group known as Stokes number is obtained, i.e.:

$$Stk = \frac{x^2\left(\rho_{\mathrm{s}} - \rho\right) v}{18\mu D_{\mathrm{c}}} \tag{70}$$

Furthermore, if the dimension x is replaced by the specific cut size, x_{50}:

$$Stk_{50} = \frac{x_{50}^2\left(\rho_{\mathrm{s}} - \rho\right) v}{18\mu D_{\mathrm{c}}} \tag{71}$$

or:

$$Stk_{50}(r) = \frac{x_{50}'^2\left(\rho_{\mathrm{s}} - \rho\right) v}{18\mu D_{\mathrm{c}}} \tag{72}$$

if the reduced cut size x_{50}' or $x_{50}(r)$ is incorporated.

5.4.3. Scale-Up at Low Concentrations

At low concentrations of the feed (less than 1 vol %), the flow pattern in a hydrocyclone is not affected by the presence of particles in the flow and particle—particle interaction is negligible. As only few particles report to the underflow, the underflow-to-throughput ratio can be assumed to have no effect on the cut size. If this is the case, the dimensional analysis gives two basic relations between the three above described dimensionless groups:

$$Stk_{50}Eu = \text{constant} \tag{73}$$

$$Eu = K_{\mathrm{p}} Re^{n_{\mathrm{p}}} \tag{74}$$

where K_{p} and n_{p} are empirical constants for a family of geometrically similar cyclones. The product $Stk_{50}Eu$ depends on the cyclone design, and on the underflow to throughput ratio. Its value range from 0.06 to 0.33. The value of n_{p} is usually between 0.0 and 0.4 [1].

5.4.4. Scale-Up at High Concentrations

At higher concentrations, the feed concentration as a fraction of volume C has to be included as an additional dimensionless group. The feed concentration of solids is a very important variable, which affects the separation efficiency and the pressure drop of a given hydrocyclone. It has been already mentioned the decreasing in efficiency as feed concentration increases. This means that the underflow-to-throughput ratio has to be increased (to allow greater volume of separated solids to be discharged). For this reason, most hydrocyclones are equipped with either a continuously variable underflow orifice, or a series of replaceable nozzles.

Theoretical and empirical approaches of the effect of feed solids concentration in hydrocyclones have appeared in the literature. Svarovsky and Marasinghe [36] have developed the following expression for the effect of high-feed solids concentration:

$$Stk_{50}(r) = k_1\,(1-R_{\mathrm{f}})\exp(k_2 C) \tag{75}$$

where $Stk_{50}(r)$ includes the reduced cut size, as already defined, while k_1 and k_2 are empirical constants, which depend on the hydrocyclone configuration as well as on solids properties. The correlation has proved to hold well for concentrations above 8 vol %, and the values of the constants k_1 and k_2 were found to be 9.05 $\times 10^{-5}$ and 6.461, respectively, for limestone and a hydrocyclone manufactured by Amberger Kaolinwerke (AKW).

5.4.5. Considerations for non-Newtonian Behavior

When fine powders are dispersed into liquids the resultant suspension is usually non-Newtonian. The non-Newtonian behavior of suspensions is normally a direct function of concentration. In this sense, the viscosity of a dilute suspension nearly equals that of the suspending liquid. Thus, when dealing with suspension of low solids contents either the apparent suspension viscosity or the suspending liquid viscosity can be used for characterization purposes. However, for more concentrated suspensions non-Newtonian behavior may be present and their viscosities cannot be considered constant anymore; their flow behavior must, therefore, be evaluated by other means.

The point above mentioned, make necessary to include parameters that characterize non-Newtonian fluids in the previously developed dimensionless groups, if they are going to be used in scale-up of hydrocyclones dealing with suspensions, which might be non-Newtonian. In this case, an approach similar to that employed in the derivation of Equation 17 may be carried out. Firstly, in this type of fluid, the drag coefficient, C_{D}, for steady-state creeping flow past a sphere based on a macroscopic momentum and energy balance of Wasserman and Slattery [47] is:

$$C_{\mathrm{D}} = \frac{24}{Re*} \tag{76}$$

where $Re*$ is a generalized Reynolds number analogous to that defined by Equation 17, being its characteristic dimension x, i.e,. the particle diameter, and $\gamma = K'(3)^{n'-1}$. Also, $K' = K[(2n'+1)/3n']^{n'}$, for this case.

For Newtonian fluids, an approximation of the drag coefficient in Stokes and the intermediate region [48] is:

$$C_{\mathrm{D}} = \left[\tfrac{24}{Re}\left(\tfrac{24}{Re}+4.5\right)\right]^{1/2} \qquad (Re<500) \tag{77}$$

a modification of Equation 77 to better fit the data is:

$$C_{\mathrm{D}} = \left[\tfrac{24}{Re^{\alpha_1}}\left(\tfrac{24}{Re^{\alpha_2}}+\alpha_3\right)\right]^{1/2} \qquad (Re*<500) \tag{78}$$

where the alpha constants are $\alpha_1 = 1.1$, $\alpha_2 = 0.2$, and $\alpha_3 = 7.5$.

By substitution of $24/Re*$ for $24/Re$ in Equation 78 and modification of the constants to ensure a friction factor of 0.44 at $Re* = 500$, the resultant non-Newtonian drag coefficient correlation is:

$$C_{\mathrm{D}} = \left[\tfrac{24}{Re*^{\alpha_1}}\left(\tfrac{24}{Re*^{\alpha_2}}+\alpha_3\right)\right]^{1/2} \qquad (\mathrm{Re}*<500) \tag{79}$$

where the alpha constant values are as previously noted.

The terminal settling velocity for non-Newtonian fluids $(Re<500)$ is found by equating Relation (77) with the generalized form of the drag coefficient, i.e.:

$$\frac{4gx}{3u_t^2}\left[\frac{\rho_{\mathrm{s}}-\rho}{\rho}\right] = \left[\frac{24}{Re*^{\alpha_1}}\left(\frac{24}{Re*^{\alpha_2}}+\alpha_3\right)\right]^{1/2} \tag{80}$$

Substituting Equation 17 and eliminating Reynolds number, Equation 80 becomes:

$$\left[\frac{gx^{n'+1}\left(\rho_s-\rho\right)}{18\gamma}\right]^2 = u_t^{2n'}+\frac{\alpha_3}{24}\left[\frac{\rho x^{n'}}{\gamma}\right]^{\alpha_2} u_t^{2n'+\alpha_2(2-n')} \quad (81)$$

For small Reynolds numbers $(\mathrm{Re}*<0.1)$, the second term of the right-hand side of Equation 81 is negligible and the simplification leads to:

$$u_\mathrm{t} = \left[\frac{gx^{n'+1}(\rho_\mathrm{s}-\rho)}{18\gamma}\right]^{1/n'} \quad (\mathrm{Re}*<0.1) \quad (82)$$

For Newtonian fluids $n' = 1$, γ equals μ, so Equation 82 becomes the familiar expression of Stokes law as described by Equation 6.

Following a similar procedure as when obtaining Stokes' number expression, Equation 82 can be equated to Equation 6, i.e.:

$$\frac{Q}{A} = \left[\frac{gx^{n'+1}\left(\rho_\mathrm{s}-\rho\right)}{18\gamma}\right]^{1/n'} \quad (83)$$

transposing for $x^{n'+1}$:

$$x^{n'+1} = \frac{18\gamma Q^{n'}}{g\left(\rho_\mathrm{s}-\rho\right)A^{n'}} \quad (84)$$

Again, considering centrifugal acceleration:

$$x^{n'+1} = \frac{18\gamma R Q^{n'}}{v_t^2\left(\rho_s-\rho\right)A^{n'}} \quad (85)$$

and, under the assumptions made before:

$$x^{n'+1} = \frac{18\gamma Q^{n'} D_\mathrm{c}}{v^2\left(\rho_\mathrm{s}-\rho\right)A^{n'}} \quad (86)$$

Substituting Q and A and rearranging terms, the Stokes number expression for non-Newtonian systems is obtained, i.e.:

$$Stk* = \frac{x^{n'+1}\left(\rho_\mathrm{s}-\rho\right)v^{2-n'}}{18\gamma D_\mathrm{c}} \quad (87)$$

It can be noticed that, again, that for Newtonian fluids this generalized Stokes number reduces to the common expression represented by Equation 12.

Finally, since concentration is an important factor in this case, replacing the reduced cut size for the simple particle size, x:

$$Stk_{50}^*(r) = \frac{x_{50}^{n'+1}(r)\left(\rho_\mathrm{s}-\rho\right)v^{2-n'}}{18\gamma D_\mathrm{c}} \quad (88)$$

in which $x_{50}(r)$ is preferred to x'_{50} in order to avoid confusion.

5.4.6. Empirical Models

An exhaustive study for concentrations up to 10 vol % was carried out by Medroho [49] in order to prove the applicability of Equations 73, 74 and 75. He employed three geometrically similar hydrocyclones of Rietema's [30] optimum geometry and obtained the following relations:

$$Stk_{50}(r)Eu = 0.047[\ln(1/R_\mathrm{f})]^{0.74}\exp(8.96C) \quad (89)$$

$$Eu = 71(Re)^{-0.116}(D_\mathrm{i}/D_\mathrm{c})^{-1.3}\exp(2.12C) \quad (90)$$

$$R_\mathrm{f} = 1218(D_\mathrm{u}/D_\mathrm{c})^{-4.75}(Eu)^{-0.30} \quad (91)$$

where R_f is the underflow-to-throughput ratio, C is the volume fraction of solids, D_i, D_c, and D_u are the inlet, body, and underflow diameters of the hydrocyclone, respectively. Covering also the low feed concentration range (i.e. up to 10 vol %), Antunes and Medroho [50] developed a set of equations bearing similarity to those presented above, but for hydrocyclones of Bradley's [2] geometry.

Ortega-Rivas and Svarovsky [51] have proposed a model for concentrated suspensions and accounting for non-Newtonian behavior of the treated slurries. They covered a feed concentration range from 5 to 25 vol % and used geometrically similar hydrocyclones following Rietema's [30] proportions. The relationships that they derived are presented below:

$$Stk_{50}^*(r)Eu = 0.006[\ln(1/R_\mathrm{f})]^{2.37}\exp(6.84C) \quad (92)$$

$$Eu = 1686(Re^*)^{-0.035}\exp(-3.39C) \quad (93)$$

$$R_\mathrm{f} = 32.8(D_\mathrm{u}/D_\mathrm{c})^{1.53}(Re^*)^{-0.34}\exp(3.70C) \quad (94)$$

where the dimensionless Reynolds and Stokes numbers include the parameters of characterization of non-Newtonian suspension previously described. Equations 92, 93 and 94 allow reliable hydrocyclones design and scale-up at concentrations up to 25 vol % of shear-thickening suspensions. They apply to Rietema's geometry, but there is some evidence suggesting that they could equally be employed to other geometries, because reasonable agreement has been found with previous models of hydrocyclone design and performance. The authors also claim that

for the case of Newtonian suspensions, i.e., low solids contents, the above mentioned equations would reduce to the common definitions so they conclude their model is of wide applicability.

All the above described relationships have the advantage of presenting graphical functions, such as the one shown in Figure 8. Those graphs can be handled for design purposes by manipulating variables and predict, in a practical manner, operation effects of hydrocyclone technology.

Figure 9. Hydrocyclone test rig

5.4.7. Practical Applications

In order to test the different models previously described in this article, experimental runs in small hydrocyclone rigs are advised. Standard geometries of cyclones, such as the RIETEMA's hydrocyclone, can be used to run tests at different diameters and pressure drops. As previously mentioned, many different design graphs describing the relationships between dimensionless groups may be available for variable manipulation and prediction of best performance variables. A hydrocyclone test rig is shown in Figure 9. The units are changeable and they may be equipped with removable underflow nozzles (Fig. 10.), in order to verify the effect that variations in the underflow orifice diameter may have in the cut size. Once a number of tests have been performed, the possible scale-up to industrial size may follow.

Figure 10. RIETEMA's proportions hydrocyclone with replaceable underflow spigots

Since cut size is a direct function of hydrocyclone diameter, the best efficiency for a number of useful applications would be given by small units. Cut sizes down to 2 μm have been reported in 10 mm diameter hydrocyclones [51]. On the other hand, also capacity is a direct function of hydrocyclone diameter, so larger units will deliver higher flow rates. Therefore, it would be necessary to reach a compromise between efficiency and capacity for industrial operation. In this sense, a basic small geometry may be kept to cut as fine particles as possible, while series arrangements may be required to render industrial capacities. A number of arrangements have been experienced, but probably the most efficient is the radial (spider) arrangement with the hydrocyclones axes horizontally placed like spokes in a wheel lying down. As shown in Figure 11, one "wheel" or hydrocyclone deck accommodates a number of "spokes" or hydrocy-

Figure 11. Diagram of radial (spider) arrangement of hydrocyclones for industrial scale

clone bodies. For cyclone cavities with a cylindrical diameter of 10 mm the diameter of the deck is 300 mm. The whole cyclone deck can be molded by injection in one piece. The feed zone is the annular space closest to the periphery. The overflow is through peripheral screw-in-vortex finders. The underflow leaves via the central circular space where the small apex openings enter.

The design feed flow per cyclone cavity is about 250 L/h corresponding to a pressure drop of 600 kPa, approximately. A deck with 20 cyclones in parallel consequently may have a capacity of 5 m^3/h. This is, however, not the maximum capacity. The cyclone cavities can be closed off individually by insertion of a blinding device in order to control the capacity. For feed flows above 5 m^3/h, the decks can be stacked on top of each other and held together by connecting rods through the inner annular space. There is a limit to the number of decks that can be stacked on top of each other. If the stack of decks becomes too high, the pressure drop over the feed zone will result in a lower inlet pressure to the cyclones furthest downstream and, consequently, these cyclones will give lower throughputs and lower efficiency. Some other arrangements have been tested with different degrees of success. Some of them have been reviewed in [1].

As has been discussed, hydrocyclone technology has numerous applications in a wide variety of industries. Hydrocyclones have been particularly used for long time in mineral processing, as well as in the oil and gas industry. In these industries, many materials can be considered inert powders, and thus the equations of the dimensionless scale-up model proposed by Medronho and Svarovsky [49] can be employed to carry out experimental tests, as suggested above. Hydrocyclones have been also successfully used in other industries, such as the food and biochemical industry. Since most materials in these industries may behave as non-Newtonian, the model suggested by Ortega-Rivas and Svarovsky [51] would be more suitable for modeling purposes of processes involving biological systems.

Some examples of application of the dimensionless scale-up model are given below.

Example 1. Predict the cut size obtained if 1 L/s of a suspension containing 5 vol % of a 2150 kg/m^3 dolomite slurry in water, is going to be separated in a 25.4 mm diameter hydrocyclone of Rietema's geometry. The available pressure is 2×10^5 Pa and the underflow orifice is 5 mm.

The relatively low concentration of suspension would allow use of the density and viscosity of water as suspending medium properties. Also, since no temperature has been given, a reasonable assumption for the water density is 1000 kg/m^3 and for the water viscosity 0.001 kg m^{-1} s^{-1}. Thus, bearing in mind to use the superficial velocity in the cyclone body, $[4Q/\pi(D_c)^2]$ as the characteristic one, the following results are obtained:

The characteristic velocity is, firstly, obtained, as defined above, i.e.:

$$v = \frac{4\,(0.001)\,m^3/s}{3.1416(0.0254)^2 m^2} = 1.97\,m/s \tag{95}$$

Then, substituting into Equation 59, the Euler number is calculated as:

$$\mathrm{Eu} = \frac{2\left(2\times10^5\right)\,\mathrm{kg/s^2{\cdot}m}}{(1000)\,\mathrm{kg/m^3}\,(1.97)\,\mathrm{m/s}} = 102.7 \tag{96}$$

As stated before, due to the low suspension concentration, the set of equations suggested for this case [49] can be considered, and thus, using Equation 91 the underflow-to-throughput ratio may be obtained as:

$$\mathrm{R_f} = 1218\left(\frac{0.005\mathrm{m}}{0.0254\mathrm{m}}\right)^{4.75}(102.7)^{-0.3} = 0.1346 \tag{97}$$

Equation 89 can then be employed to compute the value of the *Stk*$_{50}$*(r)* group, i.e.:

$$\mathrm{Stk_{50}\,(r)} = \frac{0.047[\ln\,(1/0.1346)]^{0.74}\exp\,[8.96\,(0.05)]}{102.7} = 0.0019 \tag{98}$$

Finally, transposing the cut size from the definition of the Stokes number given by Equation 72, the result is obtained as follows:

$$\mathrm{x}_{50}'^2 = \left(\frac{(0.0019)\,(18)\,(0.001)\,\mathrm{kg/m{\cdot}s}\,(0.0254)\,\mathrm{m}}{(2150-1000)\,\mathrm{kg/m^3}\,(1.97)\,\mathrm{m/s}}\right) = 1.55\times10^5\,\mathrm{m} \tag{99}$$

The cut size calculated is approximately equal to 15 μm.

Example 2. A slurry containing calcium carbonate at a concentration of 15 vol % solids, is going to be clarified using hydrocyclones of Rietema's proportions. The slurry has been characterized being non-Newtonian in behavior, with values of the parameters n' and K' of 1.39 and 2×10^{-5} kg m$^{-1} \cdot$ s$^{-(2-n)}$, respectively. The density of the slurry has been determined as 1250 kg/m^3. It is required to clarify 8 L/s of slurry, counting on a maximum pumping capacity of 315 kPa. Find out the optimum cyclone diameter and the number of units, if necessary, in order to obtain a cut size of 8 μm. Small scale experimentation has determined values of some dimensionless relationships as follows: $Stk_{50}Eu = 0.0625$, and $Eu = 720$. The calcium carbonate density has been determined as 2800 kg/m^3.

The value of the parameter n corresponds to a shear-thickening fluid, while the requirement of using Rietema's cyclones makes it possible to use the model suggested by Ortega-Rivas and Svarovsky [51]. The maximum pumping capacity would produce a pressure drop of the same value (315 000 N/m^2), because the leaving streams discharge at atmosphere conditions. Substituting the definition of superficial velocity in the cyclone body, as used in the previous example, into Equation 59, and considering the density of the slurry due to its high concentration, the following relation is obtained:

$$D_c = \sqrt[4]{\frac{(Q^2)\,(Eu)\,(\rho_m)}{(1.23)\,(\Delta P)}} \tag{100}$$

Substituting, also, the same characteristic velocity in Equation 88 and transposing for the reduced cut size:

$$x_{50}^{n'+1}\,(r) = \frac{(Stk_{50}^*)\,(18)\,(3)^{n'-1}\,(K')\,[(2n+1)\,/\,(3n)]^{n'}\,(D_c)^{5-2n'}}{(1.27Q)^{2-n'}\,(\rho_s-\rho)} \tag{101}$$

As previously stated, the cut size is directly proportional to the hydrocyclone diameter, while this diameter is inversely proportional to the flow rate. It would be, therefore, necessary to verify whether the required cut size could be obtained in a single hydrocyclone, whose diameter would match the capacity needed. If both variables do not coincide (cut size and flow rate with a single unit), iterations would be needed until a number of units is found, each of them separating the required size, while processing the appropriate fraction of the total capacity. A first approximation would consist in calculating the hydrocyclone diameter, using the first equation derived above, which will handle the 8 L/s of slurry to be treated. Once having that diameter, with the second equation, the cut size that the single unit separates, will be known. If such diameter is wider than 8 µm, the volumetric flow rate will be fractioned in equal parts to recalculate hydrocyclone diameter until a match of number of units and cut size is found. The first approximation leads to the following values:

$$D_c = \sqrt[4]{\frac{(0.008)^2\,m^6/s^2\,(720)\,(1250)\,kg/m^3}{(1.23)\,(315000)\,kg/s^2{\cdot}m}} = 0.11\ m \tag{102}$$

and:

$$x_{50}^* = \sqrt[2.39]{\frac{\left(8.68{\times}10^{-5}\right)(18)\,(1.53)\left(2{\times}10^{-5}\right)kg/m{\cdot}s^{2-n}\,(0.872)\,(0.007445)\,m^{5-2n}}{(0.0608)\,(m^3/s)^{2-n}\,(1800)\,kg/m^3}} \tag{103}$$

$$x_{50}^* = 15\,\mu m \tag{104}$$

So it is found that a 0.11 m diameter hydrocyclone will separate particles much coarser than the required cut size. By doing iterations, when fractioning the rate four times, i.e., when $Q = 0.002\,m^3/s$, a diameter of hydrocyclone $D_c = 0.055\,m$ and a cut size of 7.8×10^{-6} m are found. Therefore, the election would be the use of four units, 5.5 cm in diameter, to handle the capacity required and obtain the cut size needed.

1. Introduction

Cellular materials are widespread in everyday life and are used for cushioning, insulating, damping, construction, filtration, and many other applications. Highly porous materials combine high stiffness with very low density. Cellular materials frequently occur in nature as construction materials (e.g., wood, bone). The fact that even metals and metal alloys can be produced as cellular solids or metal foams is not as well known as the possibility to foam more traditional engineering materials such as plastics, ceramics, and glass. Metallic foams offer interesting properties due to the combination of metallic character with a porous structure.

Since ca.1960, many attempts have been made to foam metals or to produce porous metallic structures. Here some of the more important and successful procedures are described.

There is no clear-cut and generally accepted definition for the term "foam". First, one has to distinguish between liquid and solid foams. A liquid foam is a fine dispersion of gas bubbles in a liquid. Cooling a liquid foam to below the melting point of the respective material yields a frozen liquid foam which is then clearly a solid foam. What is generally meant in the context of metallic foams are in general solid metallic foams. The use of the word "solid foam" could be restricted to materials which originally were in the liquid state. However, customarily other porous structures such as sintered metal powders are often also called foams, although they never were in a liquid state. Hence, the use of the word "foam" is often extended to porous metal structures which are not actually foams, but resemble foams with respect to their high porosity, the interconnectivity of the solid material, and their irregular structure.

2. Production

2.1. Production from Metallic Melts

One group of foam-making processes starts from the molten metal, which is processed into a porous material by foaming it directly, by using an indirect method via a polymer foam, or by casting the liquid metal around solid filler materials, which reserve space for the pores or which remain in the foam.

Direct Foaming of Melts. Metallic melts can be foamed directly under certain circumstances by injecting gases into the liquid. Normally, the gas bubbles which are then formed in the metallic melt will tend to rise to its surface quickly due to the high buoyancy forces in the high-density liquid, but this can be impeded by increasing the viscosity of the molten metal. This can be done by adding fine ceramic powders or alloying elements that form particles in the melt.

Numerous attempts to foam liquid metals were undertaken in the 1960s and 1970s [1], but apparently the processes then invented could not

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.c16_c01

be sufficiently optimized to yield foams of a satisfactory quality and cost. In the 1990s, however, a number of new developments have taken place, and better production routes are now available.

Currently, there are two methods for directly foaming metallic melts. One of these is exploited by Cymat (originally by Alcan) in Canada and Hydro Aluminum in Norway [2–9] for foaming aluminum and aluminum alloys. Silicon carbide, aluminum oxide, or magnesium oxide particles are used to enhance the viscosity of the melt. The first step involves making an aluminum melt and adding 5 – 15 % of one of these particulate substances. The main problems here resemble those encountered in the production of conventional metal-matrix composites (MMCs), namely, the wetting of the particles by the melt and achieving a homogeneous distribution of the reinforcing particles [10]. The liquid MMC melt is then foamed by injection of gases (air, nitrogen, argon) with specially designed rotating impellers that produce very fine gas bubbles and distribute them homogeneously in the melt. The resulting foam floats to the surface of the melt where it can be pulled off, for example, by means of a conveyor belt. Care must be taken not to damage the foam structure by excessive shearing of the semisolid foam. The resulting material can, in principle, be as long as desired, as wide as the vessel containing the melt, and typically 10 cm thick.

The foamed material is used in the as-cast state with a closed outer surface or is cut into the required shape after foaming. Due to the high content of ceramic particles, machining of MMC foams could be problematic. The advantage of the process is the ability to produce large volumes at relatively low cost, and the low density that can be achieved. Porosities range from 80 to 97 %. A possible disadvantage is the eventual necessity for cutting the foam, thereby opening the cells, and brittleness due to reinforcing particles in the cell walls. Attempts to make shaped parts by casting the semiliquid foam into molds or by shaping the emerging foam with rolls have been undertaken [11], [12]. Some properties of such metal foams have been investigated [13], [14]. MMC foams are probably the least expensive metallic foams.

The second method of foaming melts directly is to add a foaming agent to the melt instead [15], [16], [17]. The foaming agent decomposes under the influence of heat and releases the foaming gas. In the small-scale commercial process operated at Shinko Wire in Japan, calcium is used to increase the viscosity of the melt, presumably by forming an Al_4Ca intermetallic phase, and titanium hydride TiH_2, added by using a rotating impeller, serves as the foaming agent, releasing hydrogen gas on heating. The foamed aluminum is produced in batches of approximately $2000 \times 1000 \times 600$ mm by foaming and solidification in a closed mold. Typical densities are $0.25 - 0.33$ g/cm^3. The blocks are cut into sheets of the required thickness [18] (e.g., 5 – 250 mm, standard thickness 10 mm. The pore structure of the material, known as ALPORAS, is rather uniform [19]. Mechanical [19] and sound absorption properties [20] have been measured. The material is reportedly more expensive than the MMC foams.

Solid – Gas Eutectic Solidification (Gasars). A method developed in the Ukraine [21], [22] exploits the fact that some liquid metals form a eutectic system with hydrogen gas. Dissolving hydrogen in these metals under high pressure (typically 50 bar) gives a pore-free melt in which the hydrogen is completely dissolved. Reducing the temperature and pressure causes the melt to go through the two-phase region. Below the eutectic temperature, a two-phase field corresponding to solid plus gas is reached. If the process parameters (cooling rate and pressure profile) are chosen appropriately, the gas accumulates as fine gas bubbles in the solid, thus forming a foam. The possibility of solidifying the liquid directionally offers the advantage of making foams with elongated pores. If the casting vessel is cylindrical, radial and axial pores can be made [23]. The maximum porosities that can be achieved by this process are not very high (5 – 75 %), but metals with moderate to high melting points such as copper and nickel can be foamed. The pore structure of such foams, known as gasars, is somewhat problematic [24], [25], so that further improvements have to be awaited. The mechanical properties (compression and tension) of gasars have been determined [26], [27], [28].

Investment Casting. Metal foams can also be fabricated without directly foaming the metal [29–31] by starting from a polymer foam. The

polymer foam is turned into a structure with open pores by manipulating the foaming process or by a reticulation (thermophysical shock treatment to remove residual membranes). The foam is then filled with a slurry of heat-resistant material, for example, a mixture of mullite, phenolic resin, and calcium carbonate [30]. After drying, the polymer is removed (e.g., by heating) and molten metal is cast into the resulting open voids which exactly reproduce the original foam structure. After removal of the mold material (e.g., by high-pressure water), a metallic foam is obtained that is an exact image of the original polymer foam. Figure 1 shows a micrograph of such a foam, which is being sold by ERG in California under the trade name DUOCEL. Various grades are available ranging from 2.5 to 16 pores per centimeter. Complex shaped parts can be fabricated by preforming the polymer foam. Prices are reportedly high. Aluminum alloys are usually used, but other metals can also be processed. The densities and foam morphologies are determined by the polymer foam. Porosities typically range from 80 to 97 %.

Syntactic Foams with Filler Materials. Lightweight porous metals can be produced by casting around inorganic granules or hollow spheres of low density or by infiltrating such materials with a liquid melt. A loose bulk of expanded clay granules, foamed glass spheres, or hollow aluminum oxide spheres can be used [32], [33]. The granules are then introduced into the melt, or the melt is poured over the bulk filler material. The heat capacity and conductivity of the granules is very low and therefore does not disturb the flow of the metal too much. Due to the high surface tension of the liquid metal, wetting of the granules is a problem, and in general the interstices between the granules will not be filled completely. Applying a slight vacuum or external pressure facilitates infiltration significantly. After solidification of the melt, the filler can optionally be removed, for example, by heating. A wide range of metals can be processed in this way, including aluminum, magnesium, zinc, lead, and tin. Parts of a predefined shape can be fabricated by designing a mold of the appropriate geometry. Sandwich panels have also been made [34].

2.2. Production from Metal Powders

Instead of molten metal, metal powders can be used to make porous metallic structures. Several methods can be applied. In some of these processes the powders are processed into a compact precursor material prior to the actual foaming step, in others powders (or fibers, hollow spheres, etc., which are regarded as powders here) are used for direct processing.

Fraunhofer Process. Foamed metals can be produced by a powder metallurgical method invented and patented [35–39] by the Fraunhofer-Institute IFAM in Bremen, Germany. The process begins with the mixing of metal powders (elemental metals, alloys, or powder blends) with a foaming agent, after which the blend is compacted to yield a dense, semifinished product. In principle, compaction can be performed by any technique that ensures that the foaming agent is embedded in the metal matrix without any residual open porosity, for example, uniaxial compression, extrusion, and powder rolling [34]. The choice of compaction method depends on the required shape of the precursor material. However, extrusion seems to be the most economical method at the moment and is therefore the preferred technique. Rectangular profiles with various cross sections are usually made. Thin sheets are then obtained by rolling.

Heat treatment at temperatures near the melting point of the matrix material is the next step. During this process the foaming agent, which is homogeneously distributed within the dense metallic matrix, decomposes. The released gas forces the compacted material to expand, forming a highly porous structure. Prior to foaming, the precursor material can be processed into sheets, rods, profiles, and other shapes by conventional techniques like rolling, swaging, or extrusion in order to improve the flow conditions during foaming in molds. The density of the metal foams can be controlled by adjusting the content of foaming agent and several other foaming parameters such as temperature and heating rate. If metal hydrides are used as foaming agents, a content of less than 1 % is sufficient in most cases.

Although most applications are based on aluminum foams, the Fraunhofer method is not restricted to this metal: tin, zinc, brass, lead,

Figure 1. SEM image of a metal foam made by investment casting (DUOCEL)

and some other metals and alloys can also be foamed by choosing appropriate foaming agents and process parameters. The most common alloys for foaming, however, are pure aluminum, 2xxx alloys and 6xxx alloys. Casting alloys such as AlSi7 and AlSi12 are also frequently used because of their low melting point and good foaming properties. In principle virtually any aluminum alloy can be foamed by properly adjusting the process parameters. Figure 2 shows a typical cross section of a powder metallurgical foam. The random distribution of cell sizes and shapes is typical for a foaming process.

Foaming a piece of precursor material in a furnace results in a lump of metal foam with an undefined shape unless expansion is restricted in certain directions. This is done by inserting the precursor material into a hollow mold and expanding it by heating. In this way near-net-shape parts can be prepared. Quite complicated parts can be manufactured by injecting the expanding foam into suitable molds and allowing the final expansion to occur there [40].

Sandwich panels consisting of a foamed metal core and face sheets can be obtained by gluing the face sheets to a sheet of foam. Alternatively, if a pure metallic bonding is required, conventional metal sheets (aluminum or steel) are roll-cladded onto a sheet of foamable precursor material [39]. The resulting composite can be deformed in an optional step, for example, by deep drawing. The final heat treatment then leads to sandwich structures such as those shown in Figures 3 and 4. The large aluminum/aluminum foam part shown in Figure 4 was a joint development of the car component supplier Karmann and the Fraunhofer-Institute for a concept car in which structural aluminum foam applications were demonstrated. The part is intended to replace the rear seat wall and has higher stiffness and lower weight than the conventional steel part.

Tubes can be filled with aluminum foam in various ways (Fig. 5). The easiest way is to insert a rod of foamable precursor material into the tube that is to be filled and to place the tube into a furnace. The precursor material foams and

Figure 2. Lead foam made from metal powder

Figure 3. Composite structure made of an aluminum foam core and steel face sheets (dimensions $250 \times 250 \times 20$ mm)

Figure 4. Shaped sandwich of aluminum foam with aluminum face sheets (width 1000 mm, thickness 8 mm)

eventually fills the tube completely. The disadvantage of this method is that only tubes with a significantly higher melting temperature than the material to be foamed can be used. If aluminum tubes are filled with foam in this way, the top of the tube melts during foaming because it is not supported mechanically and the heat from the furnace is not conducted into the precursor material. An alternative method is to insert a foamable tube into the tube that is to be filled. Then the foam expands towards the center of the tube. The foamable material is always in contact with the outer tube and therefore supports it. The expansion of the foam can be limited to a certain wall thickness by using a core in the center of the tube. The third possibility involves a co-extruded structure consisting of an outer tube of conventional aluminum and an inner tube of foamable precursor material. The two layers have a metallic bond, in contrast to the situation in which the inner tube is merely inserted into the outer one. This bond ensures better heat flow between the two tubes and therefore minimizes the risk of melting the outer tube. Moreover, the metallic bond between the foam and the outer tube is also better, because oxide layers between the inserted and outer tubes partially prevent a metallic bonding during foaming. Examples of foam-filled tubes are shown in Fig 6.

More details of the Fraunhofer process are given elsewhere [41–43]. Many mechanical and other physical properties have been determined [44–46]. The process is now being extended to metals with higher melting points such as iron and steel [47–49]. Due to their excellent biocompatibility, titanium foams could be used in prosthetic applications. However, these are still in the developmental stage.

Gas Entrapment. Metals can be foamed without a propellant by compressing powders into a precursor material and allowing gas to be entrapped in the metal structure during compaction [50], [51]. Heating the precursor material then leads to an expansion of the metal due to the internal pressure created by the entrapped gas. The process has mainly been used for making porous titanium structures. Titanium powder is filled into a can that is then evacuated and refilled with argon gas. The filled can is densified by hot isostatic pressing, subsequently worked, and finally foamed by heating. Refinements and extensions of this process have been developed, and properties of materials and components have been determined [52], [53].

Foaming of Slurries. Metallic foams can be produced by preparing a slurry of metal powder mixed with a foaming agent. The slurry is poured into a mold after mixing and dried at elevated temperature. The slurry becomes more viscous and starts to foam as gas begins to evolve. If sufficient stabilizing measures are taken, the expanded slurry can be dried completely to give a metal foam. Such foams have been produced from aluminum powders with orthophosphoric acid/aluminum hydroxide or hydrochloric acid as foaming agents [54]. Relative densities as low as 7 % have been achieved, but there are problems with low strength [55] and cracks in the foamed material.

Other Techniques. There are many ways to make porous metallic products from metal powders, fibers, or hollow spheres. The easiest method is to sinter loose powder fillings in a canister to give a porous material with open porosity. Mixtures of metal powders and polymer binders can be extruded and then heat treated to produce porous parts [56]. In this way porous materials with cylindrical pores can be produced. Reaction sintering of metal powder mixtures can also yield porous products.

Hollow spheres made of titanium or steel can be used to form highly porous structures by sintering [57]. Ordered and disordered arrangements can be realized. The density of such structures is extremely low with strengths that are still sufficient for many applications. By infiltrating the interstices between the hollow spheres, the strength can be increased.

2.3. Production by Deposition Techniques

Deposition techniques use metal ions as starting materials. The metal is galvanically deposited on a polymer foam with open cells [58–60]. Galvanic deposition on a polymer foam requires a certain electrical conductivity of the initial polymer foam. This is achieved by dipping the polymer foam into graphite solutions or by coating

Figure 5. Methods for filling metal tubes with metal foam [39]

Figure 6. Foam-filled aluminum tubes (Foam: AlSi12 alloy, tube: 6061 alloy)

it with a thin conductive layer by metal vaporization. After electroplating, the polymer can be removed from the metal – polymer composite by thermal treatment.

Foams of various grades can be fabricated, ranging from 2 to 30 cells per centimeter. The preferred metal is nickel or an NiCr alloy, but copper foams can also be fabricated. Foams have been offered on a commercial basis under the name RETIMET (Dunlop, Great Britan) and CELMET (Sumitomo, Japan [56]). There is also a source in Belorussia [60]. Sheets with thick-

nesses between 2 and 10 mm are available with densities ranging from 0.2 to 0.5 g/cm^3.

3. Toxicology and Occupational Health

Typically, metal foams have the same toxicological properties as the corresponding dense, base metal alloy. No specific precautions for the processing and handling of metallic foams are known.

4. Applications and Outlook

The development of aluminum-based foams has been especially promoted by the requirement for certain structural lightweight applications so that the widest range of foams is available for this metal and its alloys. Various small-scale production facilities for aluminum foams are now existent in Japan, Canada, Slovakia, Austria and Germany. Some prototypes of aluminum foam parts have been developed and tested. However, it is not yet entirely clear in all cases whether the aluminum foam part can compete with the conventional part that it is intended to replace both with respect to its physical and mechanical properties and to its economical performance.

An interesting application for three-dimensional shaped sandwich foam structures was recently presented by the car outfitter Karmann. These complex shaped panels will be used as fire walls or luggage-compartment walls and will simultaneously stiffen the entire automotive body structures [61]. A comparison of a luggage compartment wall made of conventional stamped steel with an equivalent aluminum foam sandwich panel reveals a ten times higher stiffness of the latter. A combination of this high-stiffness material with the aluminum space frame concept opens the opportunity to build different variations of vehicles – even cabriolets with their high stiffness requirements – based on one common body structure.

The cost effectiveness of the various process is difficult to evaluate and should be regarded on a part by part basis. Only few methods are suitable for high-volume mass production, and many will remain restricted to specialized applications where cost is not the most important parameter. However, some of the processes for the production of aluminum foams, especially the melt and the powder metallurgical processes, have the potential for mass production at reasonable costs. There seems to be a market for these materials in applications where the unique properties of the metallic foam are fully exploited. This is the case when the foam has multiple functions, for example, when its low weight in combination with its high-temperature resistance is desired.

1. Introduction

This article deals with the synthesis and processing of nanostructured ceramics and ceramic – metal composites. Optoelectronic materials such as porous silicon, multilayer nanostructured thin films (→ Thin Films), biomimetic materials such as hydroxyapetite, and carbon fullerenes (→ Carbon, Chap. 7.) are not covered.

Materials with fine-scale structures have long been recognized to exhibit remarkable and technologically attractive properties. Interest has been growing in a new class of ultrafine-grained materials, called nanocrystalline, nanophase, or nanostructured materials (*n*-materials) [1–3], wherein the particle or grain size is 1 – 100 nm. This interest stems not only from the outstanding properties that can be obtained from such materials, but also from the realization that early skepticism about the ability to produce high-quality nanoscale powders at a competitive cost was unfounded. Today, dozens of methods are available for producing nanopowders from metals, ceramics, and cermets, some of which have already been commercialized. Accordingly, the emphasis is shifting from powder synthesis to powder processing, i.e., the challenge of making useful coatings or bulk structures from nanopowders. Nanostructured bulk materials and protective coatings present major opportunities for advances in materials properties and performance in a broad range of engineering applications.

2. Characteristics of Nanostructured Materials

As shown in Figure 1, the general term nanostructured refers to powders, coatings/films, and

10.1002/14356007.c17_c01

bulk materials in which at least one of the phases is nanoscale [4]. In some cases, the individual powder particles are single crystals, while in others each particle may be composed of several nanocrystals. Nanocomposite materials include different combinations of metals, ceramics, and polymers. Furthermore, coatings and bulk structures can contain nanoscale closed or open porosity.

Figure 2. Fraction of atoms residing at grain boundaries as a function of grain size (width of grain boundary = 1 nm)

Table 1. Nanomaterial properties and corresponding grain/particle size effects

Nanomaterial property	Corresponding grain/particle size effects
Enhanced sinterability of metal and oxide ceramic powders	An ultrafine particle size (< 100 nm) gives rise to a high driving force for densification
Improved UV scattering	UV scattering is optimum at a particle size of 30 – 50 nm
Enhanced gas sensitivity	The gas sensitivity of a material is proportional to the surface area and hence becomes significant in nanomaterials
Very high hardness and wear resistance	Sintered nanophase metals and cermets display very high hardness and wear resistance because of their unique flow characteristics
Stable colloidal suspensions	Nanoparticles that are not agglomerated lead to increased stability of colloidal dispersions because of a smaller particle size in the liquid medium

A feature of nanoscale materials is the high fraction of atoms that reside at particle surfaces or grain boundaries. Figure 2 shows a plot of volume fraction of atoms that reside at the grain boundaries of a nanoscale material with decreasing grain size [5]. At a grain size of less than 20 nm, as much as 30 % of the atoms can be present at the grain boundaries. Accordingly, the interfaces play a crucial role in determining the mechanical, optical, and electrical properties of the material.

In general, nanoscale materials exhibit dramatic changes in properties, such as enhanced sinterability at low temperatures [6], [7], improved UV scattering [8], very high hardness and wear resistance [9], [10], enhanced gas sensitivity, [11], smaller particle size in colloidal suspensions, superior magnetic and dielectric strength, and enhanced optoelectronic properties [12]. Table 1 lists some of the unique characteristics of nanomaterials and the corresponding grain/particle size effects.

3. Production of Nanostructured Powders

Ceramic and ceramic – metal nanopowder synthesis techniques fall into two broad categories: (1) precipitation from salt solutions, and (2) condensation from the vapor phase. Specific methods have evolved that differ only in the means by which thermal and/or mechanical energy is provided to the precursor species. These include laser ablation [13], microwave plasma synthesis [14], precipitation from organometallic or aqueous salt solution [15], spray pyrolysis [16], spray conversion processing [17], and gas condensation with an evaporative source [18] or a chemical precursor [19]. At issue in each of these techniques are particle size, distribution, morphology, purity, and degree of agglomeration. While some of these processes, such as precipitation from a solution, produce very small individual particles (< 10 nm) that form larger agglomerates, others, such as spray conversion processing, produce micron-size particles consisting of grains in the 20 – 50 nm size range.

Described below are several processes in each category of nanopowder synthesis: (1) spray conversion processing (SCP) for WC/Co [17], sol – gel processing of multicomponent oxides, and aqueous solution processing (ASP) for K-doped MnO_2 [20], which involve precipitation from salt solutions, and (2) physical vapor synthesis (PVS) and chemical vapor condensation (CVC) for Al_2O_3, TiO_2, and Fe_2O_3, chemical vapor reaction (CVR) for nonoxide ceramics and liquid flame spray (LFS) for single-phase and multicomponent oxides, which involve con-

densation of nanoparticles from the gas phase. The PVS process involves evaporation of elemental species, such as Al and Fe, that are subsequently oxidized in the gas phase, while the CVC and CVR processes involve pyrolysis of vapors of organometallic compounds and halides, respectively, in a hot zone, followed by condensation. The LFS process involves injection of liquid precursor droplets into a combustion flame.

3.1. Spray Conversion Processing

Tungsten carbide/cobalt (WC/Co) hardmetal is composed of a high volume fraction (> 60 vol %) of hard WC particles that are cemented together with a much softer Co-rich binder phase. Typically, such cemented carbides are produced by mechanical mixing of the constituent WC and Co powders, followed by cold pressing and liquid-phase sintering. After sintering, the material has a characteristic bicontinuous structure, in which the WC and Co phases form interpenetrating networks in three dimensions. Such a composite structure displays high hardness, superior wear resistance, and good fracture resistance. Hence, WC/Co hardmetal is the material of choice for a host of applications, but particularly machine tools, drill bits, and wear-resistant parts.

The difficulty of uniformly mixing ultrafine WC and Co powders by mechanical means has heretofore limited the scale of the WC grain size attainable in the final sintered product to about 0.3 µm. Rutgers University and Nanodyne Inc. have developed an alternative powder processing technology, called spray conversion processing (SCP), which produces premixed powders on the submicron scale.

The production of *n*-WC/Co powders by SCP technology involves essentially three steps: (1) mixing of aqueous solutions of tungsten and cobalt salts to fix the composition of the starting solution, (2) spray drying of this solution to form a homogeneous precursor powder, and (3) fluid-bed thermochemical conversion (pyrolysis, reduction, and carburization) of the precursor powder to the desired *n*-WC/Co product powder. Using a pilot-scale production unit (Fig. 3), Nanodyne produces *n*-WC/Co powders with compositions extending over the range of commercial interest from 3 – 25 wt % Co.

3.2. Sol – Gel Processing

Sol – gel processing is a versatile method for producing not only multicomponent oxide nanopowders, but also for synthesizing nanocomposite particles. Bursill et al. [21] synthesized $BaTiO_3$ and $PbTiO_3$ nanoparticles (ca. 25 nm grain size) by the sol – gel method. Below a critical size, there is no paraelectric/ferroelectric phase transition in $BaTiO_3$. Estournes et al. [22] found that Ni nanoparticles dispersed in silica gel exhibit superparamagnetic behavior. Similarly, Piccaluga et al. synthesized $Fe_2O_3 - SiO_2$ nanocomposite particles by a gelation method using tetraethoxysilane and iron(III) nitrate as starting materials. Amorphous iron(III) oxide particles with a diameter of 3 – 4 nm were observed, which displayed superparamagnetic behavior.

To produce powders with a very high surface area (e.g., 700 m^2/g for SiO_2), Beaucage et al. [23] developed an aerosol – gel method in which the sol – gel chemistry is carried out in the gas phase.

3.3. Aqueous Solution Processing

Many methods exist for synthesizing nanopowders from aqueous solution precursors. For instance, metal chloride solutions can be reduced with sodium trialkylborohydride to form

Figure 4. Micrographs of solution synthesized K-doped MnO_2 showing (a) initial nanoparticle agglomerated structure, (b) partially transformed structure after 4 h of reflux, and (c) completely transformed nanofibrous structure after 24 h of refluxing.

2 – 5 nm metal powders, e.g., *n*-Ni and *n*-Fe. Mixed metal chloride solutions can also be employed for synthesizing alloy powders, e.g., *n*-Ni/Cr and *n*-M50 steel [24] and hydroxide and oxide powders, e.g., *n*-Ni$(OH)_x$ and yttrium-stabilized zirconia (*n*-YSZ). In addition, a procedure has been developed for synthesizing large quantities of nanopowders by ultrasonically spraying an aqueous solution of mixed salts into a tank containing the reductive solution. This method permits solution dispersal of nanoparticles in a non-agglomerated form and continuous removal of reaction byproducts.

High surface area K-doped MnO_2 nanofibers can be synthesized by reacting aqueous solutions of $KMnO_4$ and $MnSO_4$ in the presence of nitric acid, by using a refluxing technique in combination with controlled solution mixing [20]. The initial nanoparticle agglomerates are gradually transformed into a nanofibrous structure (Fig. 4). Depending critically on the synthesis conditions, the fiber diameters range from 5 to 50 nm, with lengths up to a few micrometers and spacings in the range 20 – 200 nm. The K-doped MnO_2 nanofibers are *c*-axis oriented monocrystals, and have the cryptomelane-type hollandite structure with the approximate composition KMn_8O_{16}. In this structure, about half of the available K^+ sites are occupied and the rest are empty. For this reason, this type of manganese oxide is a molecular sieve that is particularly attractive for catalytic and ion-exchange purposes. In general, such intrinsically nanoporous materials make excellent cation-exchange materials. Moreover, with surface areas of > 250 m^2/g, they are promising catalysts for oxidation reactions and ionic/electronic conductors for rechargeable batteries.

3.4. Physical Vapor Synthesis

The synthesis of nanoparticles by the physical vapor synthesis (PVS) method, first introduced by Granqvist and Buhrmann [25], and Gleiter et al. [3], [26] (Fig. 5), involves evaporation of metal species under a reduced pressure of inert gas in a ultrahigh-vacuum chamber. Nanoparticles develop in a thermalizing zone just above the evaporative source due to interactions between the hot vapor species and the much colder inert gas atoms in the chamber. These particles are convectively transported and collected on a liquid-nitrogen-cooled stainless steel drum. Oxide ceramic powders are synthesized by oxidizing the metal nanoparticles in the gas phase or after deposition on the cold finger. Subsequently, Nanophase Technologies [18] developed a continuous process that eliminates the dependence on natural convection. In this process (Fig. 6), precursor material is introduced at a controlled rate into a chamber. In the chamber, a plasma arc is formed between a nonconsumable electrode and the precursor. The precursor, typically a high-purity metal rod, passes through the plasma arc and is melted and vaporized. A reactive gas, typically oxygen, is introduced into the chamber

and reacts with the evaporated precursor, causing nanoparticles of oxides to be formed upon condensation. Additional gas is turbulently introduced to accelerate cooling of the particles. The gas propels the nanoparticles into a collector housing which contains a filter that allows the gas to exit but traps the flaky agglomerated nanocrystalline particles. The nanoparticles that collect on the filter media are periodically harvested. Nanopowders of Fe_2O_3, Al_2O_3, TiO_2, and CeO_2 are routinely produced in tonnage quantities by the PVS method under the trade name Nanotek.

Figure 5. The original gas condensation process for producing nanoparticles, introduced by GLEITER et al. [3]

A less economical method of generating metal vapors is by laser evaporation of metal targets. Alternatively, oxide targets can also be ablated to form oxide nanoparticles directly. Several researchers have used Nd:YAG, Excimer, or a CO_2 laser to generate plumes of metal vapors, which are subsequently oxidized downstream to form nanoparticles [27–29].

3.5. Chemical Vapor Condensation

The synthesis of nanoparticles by the chemical vapor condensation (CVC) method, first introduced by CHANG et al. [19], involves controlled thermal decomposition of organometallic precursors in a reduced-pressure environment. By using a hot-wall reactor and an inert carrier gas for the precursor, nonoxide ceramic nanopowders can be synthesized. Using a combustion flame reactor allows oxide ceramics to be produced (Fig. 7). A unique feature of the combustion flame/CVC process is the specially designed burner which gives a completely uniform flat combustion zone with a uniform temperature profile and gas-phase residence time over its entire surface. Thus, nanoparticles are produced that are essentially monodispersed. Furthermore, by rapidly quenching the clusters/nanoparticles as they emerge from the flame, non-agglomerated powders can be generated.

Low-pressure flat flames had not previously been investigated for purposes of nanopowder production. One study performed at low pressure [30] yielded some important information but focused on very low precursor concentrations that minimally affect the chemical flame structure. In addition, this work was performed in an open flame without a substrate. Such flames are characterized by a significantly different thermal flame structure without a quench zone after the peak flame temperature.

In contrast, atmospheric flames have been studied at great length and are routinely used for powder synthesis. The low-pressure stagnation-point flames being scaled by Nanopowder Enterprises Inc. offer some significant advantages over atmospheric-pressure synthesis [31]. First, high concentrations of flame radicals can be maintained at lower temperatures. This implies that precursor decomposition temperatures can be lower, resulting in less sintering of colliding particles. This in turn, leads to reduced agglomeration. Second, the residence times of the synthesized particles in the low-pressure environment are shorter. Both volumetric flow rates per unit burner area and distance to the stagnation plane are similar in atmospheric flame synthesis reactors, but the pressure in the combustion flame/CVC process is about 35 times lower, leading to a reduction in residence time of nearly an order of magnitude. This implies that (1) the synthesized nanoparticles in combustion flame/CVC spend substantially less time in the hot zone of the flame, and (2) the nanoparticles suffer fewer potentially agglomerating particle – particle collisions, since the overall temperatures are lower. Third, the inherent uniformity of the stagnation flow environment, coupled with the increasing strength of the thermophoretic force relative to the drag force at

Figure 6. Schematic of the Nanophase Technologies Physical Vapor Synthesis (PVS) technique [18]

low pressures, suggests that particles which condense at different radial locations will experience similar trajectories and hence time/temperature histories.

Figure 7. Schematic of the combustion flame/CVC process

3.6. Chemical Vapor Reaction

KONIG et al. [32] developed a chemical vapor reaction process at H. C. Starck and Co. for producing nanoparticles of metals and nonoxide ceramics. Precursor compounds, which are typically halides, are evaporated upstream in evaporators that are incorporated in the gas preheater. The precursor metal compounds and the reactants, which are typically H_2, CH_4, or NH_3, are introduced into the reactor through two coaxial nozzles in the form of coaxial laminar component streams. The laminar flow leads to a narrow distribution of residence times of the nuclei or particles. Thorough mixing between the flow streams is achieved by incorporating an obstacle in the otherwise strictly laminar flow, so as to generate a Karman vortex path. To prevent the reactants from being deposited on the reactor wall, to which there is a strong energetic bias, the reaction medium is screened from the reactor wall by introducing an inert gas layer. The reaction occurs at temperatures between 500 and 2000 °C, in accordance with the following examples:

$$2\,TiCl_4 + 2\,NH_3 + H_2 \longrightarrow 2\,TiN + 8\,HCl$$

$$TiCl_4 + CH_4 \longrightarrow TiC + 4\,HCl$$

$$2\,TaCl_5 + 5\,H_2 \longrightarrow 2\,Ta + 10\,HCl$$

3.7. Liquid Flame Spray

Recognizing the need to deliver precursors at high rates into a hot zone for pyrolysis, KARTHIKEYAN et al. [33] have developed a process, called liquid flame spray (LFS), in which a liquid precursor chemical is atomized, and the atomized liquid droplets are used as the spray

feedstock for producing nanoparticles. Two fluid atomizers were incorporated along the axis of an oxy-hydrogen flame spray gun. The atomizer produces micrometer-sized droplets of the liquid jet and injects them into the hot zone of the combustion flame. Nitrates, acetates, and organometallics can be dissolved in an appropriate solvent, such as isopropyl alcohol, and injected into the combustion flame. As the liquid droplets are accelerated by the flame, heat transfer from the flame to the droplets leads to evaporation of the solvent, condensation of the precursor, chemical reaction, and formation of particles in the gas phase. While the process allows the formation of a high-surface oxide material, control of particle size is an issue, as the atomizer produces a range of droplet sizes, and different droplets have different thermal histories in the spray flame, depending on their size and injection velocities.

4. Processing of Nanostructured Bulk Structures and Coatings

4.1. Equal Channel Angular Pressing

Efforts at producing dense materials from discrete metal nanopowders have met with limited success, primarily due to the inability to control oxygen contamination. Metallic nanoparticles have been produced in an ultrahigh-vacuum chamber and compacted in situ to prevent oxygen contamination [34–36]. While it has been possible to reduce the oxygen content to less than 0.5 atom % in materials such as copper, such a complicated process is less likely to be viable on an industrial scale.

Valiev et al. [37], [38] have developed an alternative approach to forming dense nanocrystalline metallic materials. Instead of consolidating powders by traditional powder metallurgy techniques, the new process, called equal channel angular (ECA) pressing, relies on severe plastic deformation to refine the microstructure. One can either start with an ingot or ball-milled powders. By extruding the material through intersecting channels of identical cross section, full consolidation and grain-size refinement are achieved simultaneously. Nanocrystalline materials of Pb – Sn, Zn – Al, and Al – Cu with a grain size of less than 100 nm, have been achieved by this process. Such materials are superplastic and display exceptional mechanical properties [39].

4.2. Liquid Phase Sintering of *n*-WC/Co

n-WC/Co powders synthesized by the SCP method are densified by liquid-phase sintering with the addition of a grain-growth inhibitor, such as VC or Cr_3C_2. In VC-doped *n*-WC/Co materials, the hardness increases with increasing VC concentration up to a maximum of 2190 VHN at 0.8 wt % VC (Fig. 8). These data correlate with a reduced mean free path for the cobalt binder phase, i.e., reduced WC grain size. Measurements also show that nanograined materials possess superior hardness at all compositions. The relatively high hardness (> 1850 VHN) at high Co content (> 10 wt %) is not accompanied by a decrease in fracture toughness [40].

Figure 8. Hardness versus VC (grain growth inhibitor) content in WC/7 wt % Co alloys

Another interesting observation is the striking difference in response of micrograined and nanograined materials to a scratch test. The micrograined material shows evidence of combined plastic deformation and fracture of the WC grains, whereas the nanograined material yields by pure plastic deformation, despite its high hardness. Evidence for superior abrasive wear resistance of *n*-WC/Co, as well as for improved cutting performance of *n*-WC/Co drill bits has been obtained [21].

4.3. Thermal Spraying of *n*-WC/Co

Thermal spraying is a widely used industrial process for applying protective coatings to materials surfaces. The coating process involves feeding prealloyed powders into a flame or plasma gun (Fig. 9). The particles are rapidly heated to form a spray of partially or completed melted droplets. The large impact forces created as these particles arrive at the substrate surface promotes strong particle to substrate adhesion and the formation of a dense coating. An attractive feature of the process is its ability to produce coatings of almost any desired material, ranging in thickness from 25 µm to several millimeters, at relatively high rates.

Nanostructured coatings of hardmetals such as WC/Co offer significant potential improvements in abrasive wear resistance and hardness compared with conventional WC/Co coatings. Preliminary work on thermal spray deposition of Nanocarb WC/12Co and WC/15Co has yielded promising results.

4.4. High-Pressure Consolidation

Using a high-pressure/high-temperature (HPHT) hot pressing unit of advanced design, developed by VORONOV et al. [41], a new class of WC/Co/diamond nanocomposites are being produced [42]. The HPHT unit consists of shaped anvils of tungsten carbide and supporting prestressed steel rings. The anvils compress a shaped insert made of lithographic stone, which transmits a near-isostatic pressure to the reaction cell. The reaction cell consists of a resistively heated graphite crucible, which is capable of reaching 2000 °C in a few minutes.

During high pressure/low temperature (HPLT) sintering, the nucleation rate of the stable phase is increased, thereby accomplishing metastable/stable phase transformation at relatively low temperature [43], [44]. For example, at 5 GPa and 600 °C, nanoparticles of γ-Al_2O_3 transform completely into α-Al_2O_3. This transformation-assisted consolidation approach is being used to fabricate fully dense materials from oxide nanoparticles.

5. Processing of Novel Nanostructured Materials

Apart from the four major powder production technologies of commercial importance (see Chap. 3), several processing methods have developed for specific materials.

5.1. Composite Nanoparticles

VOLLATH et al. [45] have developed a two-stage microwave plasma technique in which nanoparticles formed near the inlet of the reactor are coated downstream with a layer of a second material, e.g., an Al_2O_3 layer on a ZrO_2 particle. The structure of these nanocoated particles depends strongly on the crystallization behavior of the phases forming the kernel and the coating. The main applications of these new nanocoated particles may either be seen in the formation of diffusion barriers to avoid grain growth or in the modification of physical properties of the core and the chemical properties of the surface.

CHE et al. [46] have developed a modified spray pyrolysis method for the synthesis of SiO_2-encapsulated Pd nanoparticles. These composite nanoparticles were formed from a palladium nitrate solution containing ultrafine SiO_2 particles by ultrasonic spray pyrolysis. A precursor particle formed below 700 °C in the drying stage was composed of a homogeneous mixture of *n*-SiO_2 and $PdO \cdot H_2O$. When PdO was decomposed above 700 °C, metallic Pd nanoparticles were formed in the SiO_2 matrix. Because of the high surface free energy, the metallic Pd particles coagulate and condense in the interior of the composite particle. As a result of the relocation within the composite particle, SiO_2 is forced out of the particle toward the surface, and an SiO_2-encapsulated Pd particle is formed. Similar structures of $Ag-SiO_2$ and $Cu-SiO_2$ were prepared by CRANE et al [47].

5.2. Films with Nanoscale Porosity

SiO_2 films with nanoscale porosity have attractive properties such as low dielectric constant

Figure 9. Schematic of the thermal spray coating process along with the various processing parameters.

($\kappa < 2$) and low density. Such films find applications as the interlayer dielectric material in devices. Jin et al. [48] have developed a sol – gel method to form such nanoporous thin films, in which processing parameters, such as process flow for deposition and post-deposition curing, relative rates of reaction, gelation, aging, and drying, are controlled to improve mechanical properties and dielectric constant.

Skandan et al. [49] have developed a low-pressure flame deposition (LPFD) process, which utilizes the flat-flame burner described in Section 3.4. LPFD is a one-step deposition process that completely avoids the use of powders as starting material. This is beneficial in terms of significant cost reduction, as well as the ability to easily access the critical thickness range of 1 – 10 µm. The LPFD process is capable of depositing films at rates greater than 1 µm/min, up to any thickness that one desires. The experimental arrangement for operating the flat flame in film-forming mode is similar to the powder-forming mode, except that the cold plate is replaced with a heated substrate. The "superheated" clusters or nanoparticles emerging from the hot zone of the flame are allowed to impinge upon a heated substrate. The nanoparticles sinter as they arrive at the substrate and form a film or coating. The desired extent of nanoscale porosity is obtained by controlling the number density of nanoparticles in the gas phase and the temperature of the substrate.

5.3. High Green Density Compaction Method

High green density is a prerequisite for achieving a high sintered density. Due to the increased surface area in nanopowders, it is not possible to achieve high green densities when the powder is pressed at conventional pressures. Ivanov et al. [50] have developed a pulsed densification method for oxides such as Al_2O_3 and ZrO_2, in which compression waves of 100 – 500 µs in duration and up to 2.5 GPa in amplitude are generated by a pulsed magnetic press. Green compacts with densities of up to 0.8 of the theoretical density have been reported. Similar results have been obtained by cold compaction under a pressure in excess of 5 GPa [51]. Higher packing densities may be attributed to interparticle sliding and plastic deformation.

6. Applications of Nanostructured Materials

Nanopowders are used (1) as dispersed phases in fluid media, (2) on supporting substrates, (3) for consolidation into dense structures, and (4) as feedstock for the formation of films and deposition of coatings.

Some of the notable areas where nanoparticles, nanostructured sintered materials, and

nanostructured films/coatings are being used or under development are as follows.

Chemical mechanical polishing slurries, containing nanoparticle dispersions of SiO_2, Al_2O_3, and CeO_2: The field of chemical mechanical polishing (CMP) of semiconductor materials is experiencing dramatic growth. While CMP was originally a process for expensive microprocessor production by major IC manufacturers that could support its cost, it is now used for an ever widening array of products, from modem chips to DRAMs. Manufacturers are beginning to use CMP in special niches, such as silicon on insulator wafer fabrication and multichip module assembly. While the equipment, materials and process technology form the different components of the CMP process, the slurry itself is a critical element. The particle composition, size and distribution, dispersability, morphology, shape, and hardness contribute to the polishing performance. According to the National Technology Roadmap Interconnect requirements projected until 2005, there is a need for reduction in particle size extending well into the nanoscale range (< 100 nm). This is because smaller size allows finer surface finish, while non-agglomeration and narrow size distribution assure that the slurry does not scratch the surface.

Ultraviolet scatterers such as TiO_2 and ZnO have maximum UV scattering efficiency in the particle size range 30 – 50 nm. Therefore, sunscreens containing nanoparticles have a correspondingly higher sun protection factors. Furthermore, provided they are non-agglomerating, the stability of the suspension is also improved.

Cosmetic pigments such as Fe_2O_3 in the form of nanoparticles can be used in cosmetic applications because of their finer texture and ability to spread easily on a surface.

Conducting inks containing nanoparticles of Cu and Ag enable a lower sintering temperature: Cu and Ag are among the few metallic nanoparticles that are not pyrophoric and can be handled in air. Such conducting ultrafine particles are dispersed in a liquid medium and used to form fine conducting lines on plastics and ceramic substrates. The low sintering temperature (about one-third of the melting point) allows low-temperature processing, especially when dealing with polymers.

Sintered nanostructured WC/Co: As-synthesized nanophase WC/Co is milled, compacted, and liquid-phase sintered to produce a variety of tools for mining and drilling operations. The high hardness and wear resistance increases the efficiency of the drilling operation.

IR windows: Sapphire (single-crystal Al_2O_3) is presently the material of choice for IR window applications because of its superior optical and mechanical properties compared to Y_2O_3, MgO, and AlON. However, processing single-crystal components is expensive. Polycrystalline Al_2O_3, AlON, and AlN with a nanocrystalline grain size of less than one-tenth of the wavelength of radiation is being considered as a potential replacement for sapphire. The nanomaterial is expected to have superior mechanical properties and comparable optical properties, compared to sapphire.

Sputtering targets: Sputtering is a widely accepted industrial process for depositing thin films. The quality of the sputtered film depends greatly on the properties of the target, including density, composition, and grain size. Using nanoparticles as starting materials is likely to yield very high density targets that have an ultrafine microstructure and a uniform composition.

Dielectric materials: For the past several years, much emphasis has been placed on low-temperature processing of thick-film ferroelectric materials for applications in multilayer ceramic capacitors (MLCCs), transducers, sensors and actuators for the following reasons: (1) fine-grained (0.7 – 1.0 μm) ferroelectric materials that have high permittivity and very good piezoelectric properties (e.g., $\varepsilon = 4000 - 6000$ at room temperature in $BaTiO_3$, and $d = 500$ pC/N in $Pb(ZrTi)O_3$) can only be synthesized by low-temperature processing, (2) when the fabrication temperature is less than 900 °C, reactions between the electrodes and the dielectric can be significantly reduced, and (3) low-temperature processing allows replacement of the expensive AgPd electrodes with cheaper Ni and/or Cu electrodes.

Gas sensors: Thin films of oxides such as SnO_2 and TiO_2 containing nanoscale porosity have applications as gas sensors. Thin film sensors for monitoring CO, CO_2, NO_x, SO_x, and other gases are usually fabricated by depositing dense materials that have a columnar structure. The current trend is to fabricate integrated microelectronics-based gas sensors as (1) it is more economical in the long run, (2) has a faster

response time, and (3) higher sensitivity. It has already been demonstrated that a dense film with a nanoscale grain size has a faster response time. It is expected that a porous film with the grains and pores in the nanoscale regime will have an even faster response time.

Low-voltage displays: One of the areas of development for the next generation of flat panel displays is phosphor powders that have high efficiency at a low operating voltage. Doped nanoparticles of oxidic materials such as Y_2O_3:Eu and Y_2O_2S:Eu have higher cathodoluminescence efficiency at operating voltages (ca. 200 V) than their coarse-grained counterparts. It is expected that further enhancements in the performance by way of surface passivation will lead to higher photoluminescence and electroluminescence efficiencies.

Engine components: Si_3N_4 reinforced with fine particles of SiC has evolved as a high-temperature structural material. Reducing the scale of Si_3N_4 and SiC has led to improved strength and toughness. In addition, the material displays superplastic behavior.

7. Future Perspective
